FEATURES

Very low power
  330 μA supply current
Extremely low harmonic distortion
  −126 HD2 at 10 kHz
  −128 HD3 at 10 kHz
Fully differential or single-ended inputs/outputs
Differential output designed to drive precision ADCs
  Drives switched capacitor and Σ-Δ ADCs
  Rail-to-rail outputs
VOCM pin adjusts output common mode
Robust overvoltage up to 18 V beyond supplies
High performance
  Suitable for driving 16-bit converter up to 250 kSPS
  39 nV/√Hz output noise
  1 ppm/°C gain drift maximum
  200 μV maximum output offset
  10 V/μs slew rate
  6 MHz bandwidth
Single supply: 3 V to 18 V
Dual supplies: ±1.5 V to ±9 V

APPLICATIONS

ADC driver
Differential instrumentation amplifier building block
Single-ended-to-differential converter
Battery-powered instruments

GENERAL DESCRIPTION

The AD8476 is a very low power, fully differential precision amplifier with integrated gain resistors for unity gain. It is an ideal choice for driving low power, high performance ADCs as a single-ended-to-differential or differential-to-differential amplifier. It provides a precision gain of 1, common-mode level shifting, low temperature drift, and rail-to-rail outputs for maximum dynamic range.

The AD8476 also provides overvoltage protection from large industrial input voltages up to ±23 V while operating on a dual 5 V supply. Power dissipation on a single 5 V supply is only 1.5 mW.

The AD8476 works well with SAR, Σ-Δ, and pipeline converters. The high current output stage of the part allows it to drive the switched capacitor front-end circuits of many ADCs with minimal error.

Unlike many differential drivers on the market, the AD8476 is a high precision amplifier. With 200 μV maximum output offset, 39 nV/√Hz noise, and −102 dB THD + N at 10 kHz, the AD8476 pairs well with low power, high accuracy converters.

Considering its low power consumption and high precision, the slew-enhanced AD8476 has excellent speed, settling to 16-bit precision for 250 kSPS acquisition times.

The AD8476 is available in space-saving 16-lead, 3 mm × 3 mm LFCS and 8-lead MSOP packages. It is fully specified over the −40°C to +125°C temperature range.

# MAXIMUM POWER DISSIPATION

The maximum safe power dissipation for the AD8476 is limited by the associated rise in junction temperature (Tj) on the die. At approximately 150°C, which is the glass transition temperature, the properties of the plastic change. Even temporarily exceeding this temperature limit may change the stresses that the package exerts on the die, permanently shifting the parametric performance of the amplifiers. Exceeding a temperature of 150°C for an extended period may result in a loss of functionality.

# ESD CAUTION

ESD (electrostatic discharge) sensitive device. Charged devices and circuit boards can discharge without detection. Although this product features patented or proprietary protection circuitry, damage may occur on devices subjected to high energy ESD. Therefore, proper ESD precautions should be taken to avoid performance degradation or loss of functionality.

TERMINOLOGY

Differential Voltage
Differential voltage refers to the difference between two node voltages. For example, the output differential voltage (or equivalently, output differential mode voltage) is defined as

\[ V_{OUT, dm} = (V_{+OUT} - V_{-OUT}) \]

where \( V_{+OUT} \) and \( V_{-OUT} \) refer to the voltages at the +OUT and –OUT terminals with respect to a common ground reference. Similarly, the differential input voltage is defined as

\[ V_{IN, dm} = (V_{+IN} - V_{-IN}) \]

Common-Mode Voltage
Common-mode voltage refers to the average of two node voltages with respect to the local ground reference. The output common-mode voltage is defined as

\[ V_{OUT, cm} = \frac{V_{+OUT} + V_{-OUT}}{2} \]

Balance
Output balance is a measure of how close the output differential signals are to being equal in amplitude and opposite in phase. Output balance is most easily determined by placing a well-matched resistor divider between the differential voltage nodes and comparing the magnitude of the signal at the divider midpoint with the magnitude of the differential signal. By this definition, output balance is the magnitude of the output common-mode voltage divided by the magnitude of the output differential mode voltage.

\[ \text{Output Balance Error} = \left| \frac{\Delta V_{OUT, cm}}{\Delta V_{OUT, dm}} \right| \]
THEORY OF OPERATION

OVERVIEW

The AD8476 is a fully differential amplifier, with integrated laser-trimmed resistors, that provides a precision gain of 1. The internal differential amplifier of the AD8476 differs from conventional operational amplifiers in that it has two outputs whose voltages are equal in magnitude, but move in opposite directions (180° out of phase).

The AD8476 is designed to greatly simplify single-ended-to-differential conversion, common-mode level shifting and precision driving of differential signals into low power, differential input ADCs. The VO CM input allows the user to set the output common-mode voltage to match with the input range of the ADC. Like an operational amplifier, the VO CM function relies on high open-loop gain and negative feedback to force the output nodes to the desired voltages.

Due to the internal common-mode feedback loop and the fully differential topology of the amplifier, the AD8476 outputs are precisely balanced over a wide frequency range. This means that the amplifier's differential outputs are very close to the ideal of being identical in amplitude and exactly 180° out of phase.

DC PRECISION

The dc precision of the AD8476 is highly dependent on the accuracy of its integrated gain resistors. Using superposition to analyze the circuit shown in Figure 52, the following equation shows the relationship between the input and output voltages of the amplifier:

\[ V_{IN,dm} \left( R_p - R_N \right) + V_{IN,dm} \frac{1}{2} \left( 2R_p R_N + R_p + R_N \right) \]

\[ = V_{OUT,dm} \left( R_p - R_N \right) + V_{OUT,dm} \frac{1}{2} \left( 2R_p + R_N \right) \]

where:

\[ R_p = \frac{R_{FP}}{R_{GP}}, \quad R_N = \frac{R_{FN}}{R_{GN}} \]

\[ V_{IN,dm} = V_p - V_N \]

\[ V_{IN,dm} = \frac{1}{2} (V_p + V_N) \]

The differential closed-loop gain of the amplifier is

\[ \frac{V_{OUT,dm}}{V_{IN,dm}} = \frac{2R_p R_N + R_p + R_N}{2 + R_p + R_N} \]

and the common rejection of the amplifier is

\[ \frac{V_{OUT,dm}}{V_{IN,dm}} = \frac{2(R_p - R_N)}{2 + R_p + R_N} \]

The preceding equations show that the gain accuracy and the common-mode rejection (CMRR) of the AD8476 are determined primarily by the matching of the feedback networks (resistor ratios). If the two networks are perfectly matched, that is, if \( R_p \) and \( R_N \) equal \( R_{FP}/R_{GP} \), then the resistor network does not generate any CMRR errors and the differential closed loop gain of the amplifier reduces to

\[ \frac{V_{OUT,dm}}{V_{IN,dm}} = \frac{RF}{RG} \]
The AD8476 integrated resistors are precision wafer-laser-trimmed to guarantee a minimum CMRR of 90 dB (32 μV/V), and gain error of less that 0.02%. To achieve equivalent precision and performance using a discrete solution, resistors must be matched to 0.01% or better.

**INPUT VOLTAGE RANGE**

The AD8476 can measure input voltages as large as the supply rails. The internal gain and feedback resistors form a divider, which reduces the input voltage seen by the internal input nodes of the amplifier. The largest voltage that can be measured properly is constrained by the output range of the amplifier and the capability of the amplifier’s internal summing nodes. This voltage is defined by the input voltage, and the ratio between the feedback and the gain resistors.

Figure 53 shows the voltage at the internal summing nodes of the amplifier, defined by the input voltage and internal resistor network. If $V_N$ is grounded, the expression shown reduces to

$$V_{PLUS} = V_{MINUS} = \frac{RG}{RF + RG} \left( VOCM + \frac{1}{2} \frac{RF}{RG} V_P \right)$$

The internal amplifier of the AD8476 has rail-to-rail inputs. To obtain accurate measurements with minimal distortion, the voltage at the internal inputs of the amplifier must stay below $+V_S - 1$ V and above $-V_S$.

The AD8476 provides overvoltage protection for excessive input voltages beyond the supply rails. Integrated ESD protection diodes at the inputs prevent damage to the AD8476 up to $+V_S + 18$ V and $-V_S - 18$ V.

**DRIVING THE AD8476**

Care should be taken to drive the AD8476 with a low impedance source: for example, another amplifier. Source resistance can unbalance the resistor ratios and, therefore, significantly degrade the gain accuracy and common-mode rejection of the AD8476. For the best performance, source impedance to the AD8476 input terminals should be kept below 0.1 Ω. Refer to the DC Precision section for details on the critical role of resistor ratios in the precision of the AD8476.

**POWER SUPPLIES**

The AD8476 operates over a wide range of supply voltages. It can be powered on a single supply as low as 3 V and as high as 18 V. The AD8476 can also operate on dual supplies from ±1.5 V to ±9 V.

A stable dc voltage should be used to power the AD8476. Note that noise on the supply pins can adversely affect performance. For more information, see the PSRR performance curve in Figure 10.

Place a bypass capacitor of 0.1 μF between each supply pin and ground, as close as possible to each supply pin. Use a tantalum capacitor of 10 μF between each supply and ground. It can be farther away from the supply pins and, typically, it can be shared by other precision integrated circuits.

APPLICATIONS INFORMATION

TYPICAL CONFIGURATION

The AD8476 is designed to facilitate single-ended-to-differential conversion, common-mode level shifting, and precision processing of signals so that they are compatible with low voltage ADCs.

Figure 54 shows a typical connection diagram of the AD8476.

SINGLE-ENDED-TO-DIFFERENTIAL CONVERSION

Many industrial systems have single-ended inputs from input sensors; however, the signals are frequently processed by high performance differential input ADCs for higher precision. The AD8476 performs the critical function of precisely converting single-ended signals to the differential inputs of precision ADCs, and it does so with no need for external components.

To convert a single-ended signal to a differential signal, connect one input to the signal source and the other input to ground (see Figure 54). Note that either input can be driven by the source with the only effect being that the outputs have reversed polarity. The AD8476 also accepts truly differential input signals in precision systems with differential signal paths.

SETTING THE OUTPUT COMMON-MODE VOLTAGE

The VOCM pin of the AD8476 is internally biased by a precision voltage divider comprising of two 1 MΩ resistors between the supplies. This divider level shifts the output to midsupply. Relying on the internal bias results in an output common-mode voltage that is within 0.05% of the expected value.

In cases where control of the output common-mode level is desired, an external source or resistor divider can be used to drive the VOCM pin. If driven directly from a source, or with a resistor divider of unequal resistor values, the resistance seen by the VOCM pin should be less than 1 kΩ. If an external voltage divider consisting of equal resistor values is used to set VOCM to midsupply, higher values can be used because the external resistors are placed in parallel with the internal resistors. The output common-mode offset listed in the Specifications section assumes that the VOCM input is driven by a low impedance voltage source.

Because of the internal divider, the VOCM pin sources and sinks current, depending on the externally applied voltage and its associated source resistance.

It is also possible to connect the VOCM input to the common-mode level output of an ADC; however, care must be taken to ensure that the output has sufficient drive capability. The input impedance of the VOCM pin is 500 kΩ. If multiple AD8476 devices share one ADC reference output, a buffer may be necessary to drive the parallel inputs.

1 Depending on measurement/application type, check that the AD8476 meets settling time requirements.
LOW POWER ADC DRIVING

The AD8476 is designed to be a low power driver for ADCs with up to 16-bit precision and sampling rates of up to 250 kSPS. The circuit in Figure 56 shows the AD8476 driving the AD7687, a 16-bit, 250 kSPS fully differential SAR ADC. The filter between the AD8476 and the ADC reduces high frequency noise and reduces switching transients from the sampling of the ADC.

Choose the values of this filter with care. Optimal values for the filter may need to be determined empirically, but the guidelines discussed herein are provided to help the user. For optimum performance, this filter should be fast enough to settle full-scale to 0.5 LSB of the ADC within the acquisition time specified in the ADC data sheet, in this case, the AD7687. If the filter is slower than the acquisition time, distortion can result that looks like harmonics. If the filter is too fast, the noise bandwidth of the amplifier increases, thereby reducing the SNR of your system.

Additional considerations help determine the values of the individual components. THD of the ADC is likely to increase with source resistance. This is stated in the ADC data sheet. To reduce this effect, try to use smaller resistance and larger capacitance. Large capacitance values much greater than 2 nF are hard for the amplifier to drive. Higher capacitance also increases the effect of changes in output impedance.

It is also important to consider the signal frequency range of interest. The AD8476 THD decreases with higher frequency (see Figure 42) and output impedance increases with higher frequency (see Figure 49). This higher output impedance yields slower settling, thus be certain to choose your capacitance so that the filter still meets the settling requirement at the maximum frequency of interest.

In the application shown, a 100 Ω resistors and 2.2 nF capacitors at each output were chosen. For driving the AD7687, this combination yields an SNR loss of 2.5 dB and good THD performance for a 20 kHz fundamental frequency, with an ADC throughput rate of 250kSPS. The filter bandwidth can be determined by the following equation:

\[
\text{Filter Frequency} = \frac{1}{2\pi RC}
\]
