FEATURES
High accuracy supports 50 Hz/60 Hz IEC 62053-21
Less than 0.1% error over a dynamic range of 500 to 1
Compatible with 3-phase, 3-wire delta and 3-phase, 4-wire Wye configurations
Supplies average active power on the frequency outputs F1 and F2
High frequency output (CF) is intended for calibration and supplies instantaneous active power
Logic output REVP indicates a potential miswiring or negative power on the sum of all phases
Direct drive for electromechanical counters and 2-phase stepper motors (F1 and F2)
Proprietary ADCs and DSP provide high accuracy over large variations in environmental conditions and time
On-chip power supply monitoring
On-chip creep protection (no load threshold)
On-chip reference 2.4 V ± 8% (25 ppm/°C typical) with external overdrive capability
Single 5 V supply, low power (42.5 mW typical)
Low cost CMOS process

GENERAL DESCRIPTION
The ADE7752B is a high accuracy polyphase electrical energy measurement IC. The ADE7752B specifications surpass the accuracy requirements as quoted in the IEC62053-21 standard.

The only analog circuitry used in the ADE7752B is in the analog-to-digital converters (ADCs) and reference circuit. All other signal processing (for example, multiplication, filtering, and summation) is carried out in the digital domain. This approach provides superior stability and accuracy over extremes in environmental conditions and over time.
The ADE7752B supplies average active power information on the low frequency outputs, F1 and F2. These logic outputs can be used to directly drive an electromechanical counter or to interface with a microcontroller (MCU). The CF logic output gives instantaneous active power information. This output is intended to be used for calibration purposes.
The ADE7752B includes a power supply monitoring circuit on the VDD pin. The ADE7752B remains inactive until the supply voltage on VDD reaches 4 V. If the supply falls below 4 V, the ADE7752B resets and no pulses are issued on F1, F2, and CF. Internal phase matching circuitry ensures that the voltage and current channels are phase matched. An internal no load threshold ensures that the ADE7752B does not exhibit any creep when there is no load.
The ADE7752B is available in a 24-lead SOIC package.

Stresses above those listed under Absolute Maximum Ratings may cause permanent damage to the device. This is a stress rating only; functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

**ESD CAUTION**

**ESD (electrostatic discharge) sensitive device.**

Charged devices and circuit boards can discharge without detection. Although this product features patented or proprietary protection circuitry, damage may occur on devices subjected to high energy ESD. Therefore, proper ESD precautions should be taken to avoid performance degradation or loss of functionality.
PIN CONFIGURATION AND FUNCTION DESCRIPTIONS

Figure 8. Error As a Percent of Reading over Frequency with an Internal Reference (Wye Connection)

Figure 9. Error As a Percent of Reading over Power Supply with Internal Reference (Wye Connection)
**TERMINOLOGY**

**Measurement Error**
The error associated with the energy measurement made by the ADE7752B is defined by the following formula:

\[
\text{Percentage Error} = \left( \frac{\text{Energy Registered by ADE7762} - \text{True Energy}}{\text{True Energy}} \right) \times 100\% \quad (1)
\]

**Error Between Channels**
The high-pass filter (HPF) in the current channel has a phase lead response. To offset this phase response and equalize the phase response between channels, a phase correction network is placed in the current channel. The phase correction network ensures a phase match between the current channels and the voltage channels to within ±0.1° over a range of 45 Hz to 65 Hz and ±0.2° over a range of 40 Hz to 1 kHz (see Figure 21 and Figure 22).

**Power Supply Rejection (PSR)**
This quantifies the ADE7752B measurement error as a percentage of reading when the power supplies are varied.

For the ac PSR measurement, a reading at a nominal supply (5 V) is taken. A 200 mV rms/100 Hz signal is then introduced onto the supply and a second reading is obtained under the same input signal levels. Any error introduced is expressed as a percentage of reading. See the definition for Measurement Error.

For the dc PSR measurement, a reading at nominal supplies (5 V) is taken. The supply is then varied ±5% and a second reading is obtained with the same input signal levels. Any error introduced is again expressed as a percentage of reading.

**ADC Offset Error**
This refers to the dc offset associated with the analog inputs to the ADCs. It means that with the analog inputs connected to AGND, the ADCs still see an analog input signal offset. However, because the HPF is always present, the offset is removed from the current channel and the power calculation is not affected by this offset.

**Gain Error**
The gain error of the ADE7752B is defined as the difference between the measured output frequency (minus the offset) and the ideal output frequency. The difference is expressed as a percentage of the ideal frequency. The ideal frequency is obtained from the ADE7752B transfer function (see the Transfer Function section).
Figure 10. Test Circuit for Performance Curves
**THEORY OF OPERATION**

The six signals from the current and voltage transducers are digitized with ADCs. These ADCs are 16-bit, second-order ΔΣ with an oversampling rate of 833 kHz. This analog input structure greatly simplifies transducer interface by providing a wide dynamic range and bipolar input for direct connection to the transducer. High-pass filters in the current channels remove the dc component from the current signals. This eliminates any inaccuracies in the active power calculation due to offsets in the voltage or current signals (see the HPF and Offset Effects section).

The active power calculation is derived from the instantaneous power signal. The instantaneous power signal is generated by a direct multiplication of the current and voltage signals of each phase. To extract the active power component, the dc component, the instantaneous power signal is low-pass filtered on each phase. Figure 11 illustrates the instantaneous active power signal and shows how the active power information can be extracted by low-pass filtering the instantaneous power signal. This method is used to extract the active power information on each phase of the polyphase system. The total active power information is then obtained by adding the individual phase active power. This scheme correctly calculates active power for nonsinusoidal current and voltage waveforms at all power factors. All signal processing is carried out in the digital domain for superior stability over temperature and time.

The low frequency output of the ADE7752B is generated by accumulating the total active power information. This low frequency inherently means a long accumulation time between output pulses. The output frequency is therefore proportional to the average active power. This average active power information can, in turn, be accumulated (for example, by a counter) to generate active energy information. Because of its high output frequency and, therefore, shorter integration time, the CF output is proportional to the instantaneous active power. This pulse is useful for system calibration purposes that take place under steady load conditions.

**POWER FACTOR CONSIDERATIONS**

Low-pass filtering, the method used to extract the active power information from the individual instantaneous power signal, is still valid when the voltage and current signals of each phase are not in phase. Figure 11 illustrates the instantaneous active power signal and shows how the active power information can be extracted by low-pass filtering the instantaneous power signal. This method is used to extract the active power information on each phase of the polyphase system. The total active power information is then obtained by adding the individual phase active power. This scheme correctly calculates active power for nonsinusoidal current and voltage waveforms at all power factors. All signal processing is carried out in the digital domain for superior stability over temperature and time.

This is the correct active power calculation.
NONSINUSOIDAL VOLTAGE AND CURRENT

The active power calculation method also holds true for non-sinusoidal current and voltage waveforms. All voltage and current waveforms in practical applications have some harmonic content. Using the Fourier transform, instantaneous voltage and current waveforms can be expressed in terms of their harmonic content

\[ v(t) = V_0 + \sqrt{2} \times \sum_{n=1}^{\infty} V_n \times \sin\left(n\omega t + \alpha_n\right) \]  

(3)

where:

- \( v(t) \) is the instantaneous voltage.
- \( V_0 \) is the average value.
- \( V_n \) is the rms value of voltage harmonic \( n \).
- \( \alpha_n \) is the phase angle of the voltage harmonic.

\[ i(t) = I_0 + \sqrt{2} \times \sum_{n=1}^{\infty} I_n \times \sin\left(n\omega t + \beta_n\right) \]  

(4)

where:

- \( i(t) \) is the instantaneous current.
- \( I_0 \) is the dc component.
- \( I_n \) is the rms value of current harmonic \( n \).
- \( \beta_n \) is the phase angle of the current harmonic.

Using Equation 3 and Equation 4, the active power, \( P \), can be expressed in terms of its fundamental active power (\( P_1 \)) and harmonic active power (\( P_H \)).

\[ P = P_1 + P_H \]

where:

\[ P_1 = V_1 \times I_1 \cos \phi_1 \]  

(5)

\[ \phi_1 = \alpha_1 - \beta_1 \]

\[ P_H = \sum_{n=1}^{\infty} V_n \times I_n \cos \phi_n \]  

(6)

\[ \phi_n = \alpha_n - \beta_n \]

As can be seen from Equation 6, a harmonic active power component is generated for every harmonic, provided that harmonic is present in both the voltage and current waveforms. The power factor calculation has been shown to be accurate in the case of a pure sinusoid. Therefore, the harmonic active power also correctly accounts for power factor because harmonics are made up of a series of pure sinusoids. A limiting factor on harmonic measurement is the bandwidth. On the ADE7752B, the bandwidth of the active power measurement is 14 kHz with a master clock frequency of 10 MHz.
**ANALOG INPUTS**

**CURRENT CHANNELS**

The voltage outputs from the current transducers are connected to the ADE7752B current channels, which are fully differential voltage inputs. IAP, IBP, and ICP are the positive inputs for IAN, IBN, and ICN, respectively.

The maximum peak differential signal on the current channel should be less than ±500 mV (353 mV rms for a pure sinusoidal signal) for the specified operation.

The maximum signal levels on IAP and IAN are shown in Figure 13. The maximum differential voltage between IAP and IAN is ±500 mV. The differential voltage signal on the inputs must be referenced to a common mode, for example, AGND. The maximum common-mode signal shown in Figure 13 is ±25 mV.

![Figure 13. Maximum Signal Levels, Current Channel](image)

**VOLTAGE CHANNELS**

The output of the line voltage transducer is connected to the voltage inputs of the ADE7752B. Voltage channels are pseudo-differential voltage inputs. VAP, VBP, and VCP are the positive inputs with respect to VN.

The maximum peak differential signal on the voltage channel is ±500 mV (353 mV rms for a pure sinusoidal signal) for specified operation.

Figure 14 illustrates the maximum signal levels that can be connected to the ADE7752B voltage channels.

Voltage channels must be driven from a common-mode voltage, that is, the differential voltage signal on the input must be referenced to a common mode (usually AGND). The analog inputs of the ADE7752B can be driven with common-mode voltages of up to 25 mV with respect to AGND. However, best results are achieved using a common mode equal to AGND.

![Figure 14. Maximum Signal Levels, Voltage Channel](image)
TYPICAL CONNECTION DIAGRAMS

CURRENT CHANNEL CONNECTION

Figure 15 shows a typical connection diagram for the current channel (IA). A current transformer (CT) is the current transducer selected for this example. Notice that the common-mode voltage for the current channel is AGND and is derived by center-tapping the burden resistor to AGND. This provides the complementary analog input signals for IAP and IAN. The CT turns ratio and burden resistor Rb are selected to give a peak differential voltage of ±500 mV at maximum load.

In theory, it is better to center tap Rb; however, this requires very careful attention to the layout and matching of the resistors to ensure that the channels have the same resistance. A single resistor may be more practical and is a valid design choice.

![Figure 15. Typical Connection for Current Channels](image)

VOLTAGE CHANNEL CONNECTION

Figure 16 shows two typical connections for the voltage channel. The first option uses a potential transformer (PT) to provide complete isolation from the main voltage. In the second option, the ADE7752B is biased around the neutral wire, and a resistor divider is used to provide a voltage signal proportional to the line voltage. Adjusting the ratio of Ra, Rb, and VR is a convenient way of carrying out a gain calibration on the meter. VR can be implemented using either a potentiometer or a binary weighted series of resistors. Either configuration works, however, the potentiometer is subject to noise over time. Two fixed value resistors can be used in place of VR to minimize the noise.

![Figure 16. Typical Connections for Voltage Channels](image)

METER CONNECTIONS

In 3-phase service, two main power distribution services exist: 3-phase, 4-wire or 3-phase, 3-wire. The additional wire in the 3-phase, 4-wire arrangement is the neutral wire. The voltage lines have a phase difference of ±120° (±2π/3 radians) between each other (see Equation 7).

\[ V_A(t) = \sqrt{2} \times V_a \times \cos(\omega t + \phi_A) \]
\[ V_B(t) = \sqrt{2} \times V_b \times \cos(\omega t + \frac{2\pi}{3} + \phi_B) \]
\[ V_C(t) = \sqrt{2} \times V_c \times \cos(\omega t + \frac{4\pi}{3} + \phi_C) \]

where \( V_a, V_b, \) and \( V_c \) represent the voltage rms values of the different phases.

The current inputs are represented by

\[ I_A(t) = \sqrt{2} I_A \times \cos(\omega t + \phi_A) \]
\[ I_B(t) = \sqrt{2} I_B \times \cos(\omega t + \frac{2\pi}{3} + \phi_B) \]
\[ I_C(t) = \sqrt{2} I_C \times \cos(\omega t + \frac{4\pi}{3} + \phi_C) \]

where:
\( I_A, I_B, \) and \( I_C \) represent the rms value of the current of each phase.
\( \phi_A, \phi_B, \) and \( \phi_C \) represent the phase difference of the current and voltage channel of each phase.

The instantaneous powers can then be calculated as follows:

\[ P_A(t) = V_A(t) \times I_A(t) \]
\[ P_B(t) = V_B(t) \times I_B(t) \]
\[ P_C(t) = V_C(t) \times I_C(t) \]

Then:

\[ P_A(t) = V_A \times I_A \times \cos(\phi_A) - V_A \times I_A \times \cos(2\omega t + \phi_A) \]
\[ P_B(t) = V_B \times I_B \times \cos(\phi_B) - V_B \times I_B \times \cos(2\omega t + \frac{4\pi}{3} + \phi_B) \]
\[ P_C(t) = V_C \times I_C \times \cos(\phi_C) - V_C \times I_C \times \cos(2\omega t + \frac{8\pi}{3} + \phi_C) \]

As shown in Equation 9, the active power calculation per phase is made when current and voltage inputs of one phase are connected to the same channel (A, B, or C). Then the summation of each individual active power calculation gives the total active power information, \( P(t) = P_A(t) + P_B(t) + P_C(t) \).
Figure 17 shows the connections of the ADE7752B analog inputs with the power lines in a 3-phase, 3-wire delta service.

![Diagram of ADE7752B connections for 3-phase, 3-wire delta service](image)

*Ra >> Rf + VR; *Rb + VR = Rf

Figure 17. 3-Phase, 3-Wire Meter Connection with ADE7752B

Note that only two current inputs and two voltage inputs of the ADE7752B are used in this case. The active power calculated by the ADE7752B does not depend on the selected channels.

Figure 18 shows the connections of the ADE7752B analog inputs with the power lines in a 3-phase, 4-wire Wye service.

![Diagram of ADE7752B connections for 3-phase, 4-wire Wye service](image)

Figure 18. 3-Phase, 4-Wire Meter Connection with ADE7752B
POWER SUPPLY MONITOR

The ADE7752B contains an on-chip power supply monitor. The power supply (VDD) is monitored continuously. At power-up, when the supply is less than 4 V ± 2% and VREF is less than 1.9 V (typical), the outputs of the ADE7752B are inactive and the data path is held in reset. Once VDD is greater than 4 V ± 2% and VREF is greater than 1.9 V (typical), the chip is active and energy accumulation begins. At power-down, when VDD falls below 4 V or VREF falls below 1.9 V (typical), the data path is again held in reset. This implementation ensures correct device operation at power-up and at power-down. The power supply monitor has built-in hysteresis and filtering. This gives a high degree of immunity to false triggering due to noisy supplies.

The power supply and decoupling for the part should be such that the ripple at VDD does not exceed ±5% as specified for normal operation.

![Figure 19. On-Chip Power Supply Monitor](image)
HPF AND OFFSET EFFECTS

Figure 20 shows the effect of offsets on the active power calculation. An offset on the current channel and the voltage channel contributes a dc component after multiplication, as shown in Figure 20. Because this dc component is extracted by the LPF and is used to generate the active power information for each phase, the offsets can contribute a constant error to the total active power calculation. The HPF in the current channels avoids this problem easily. By removing the offset from at least one channel, no error component can be generated at dc by the multiplication. Error terms at \( \cos(\omega t) \) are removed by the LPF and the digital-to-frequency conversion (see the Digital-to-Frequency Conversion section).

\[
\left| V \cos(\omega t) + V_{OS} \right| \times \left| I \cos(\omega t) + I_{OS} \right| = \\
\frac{V \times I}{2} + V_{OS} \times I_{OS} + V_{OS} \times I \cos(\omega t) + I_{OS} \times V \cos(\omega t) \\
+ \frac{V \times I}{2} \times \cos(2\omega t)
\]

The ADE7752B is phase compensated up to 1 kHz as shown. This ensures correct active harmonic power calculation even at low power factors.
DIGITAL-TO-FREQUENCY CONVERSION

After multiplication, the digital output of the low-pass filter contains the active power information of each phase. However, because this LPF is not an ideal brick wall filter implementation, the output signal also contains attenuated components at the line frequency and its harmonics, that is, \( \cos(h\omega t) \), where \( h = 1, 2, 3 \ldots \)

The magnitude response of the filter is given by

\[
|H(f)| = \frac{1}{\sqrt{1 + \left| \frac{f}{8} \right|^2}}
\]

where the −3 dB cutoff frequency of the low-pass filter is 8 Hz.

For a line frequency of 50 Hz, this gives an attenuation of the \( 2\omega \) (100 Hz) component of approximately −22 dB. The dominating harmonic is twice the line frequency, that is, \( \cos(2\omega t) \), due to the instantaneous power signal. Figure 23 shows the instantaneous active power signal at the output of the CF, which still contains a significant amount of instantaneous power information, \( \cos(2\omega t) \).

This signal is then passed to the digital-to-frequency converter where it is integrated (accumulated) over time to produce an output frequency. This accumulation of the signal suppresses or averages out any nondc component in the instantaneous active power signal.

The average value of a sinusoidal signal is zero. Thus, the frequency generated by the ADE7752B is proportional to the average active power. Figure 23 shows the digital-to-frequency conversion for steady load conditions, that is, constant voltage and current.

The frequency output CF varies over time, even under steady load conditions (see Figure 23). This frequency variation is primarily due to the \( \cos(2\omega t) \) components in the instantaneous active power signal. The output frequency on CF can be up to 160× higher than the frequency on F1 and F2. The higher output frequency is generated by accumulating the instantaneous active power signal over a much shorter time, while converting it to a frequency. This shorter accumulation period means less averaging of the \( \cos(2\omega t) \) component. Therefore, some of this instantaneous power signal passes through the digital-to-frequency conversion.

Where CF is used for calibration purposes, the frequency counter should average the frequency to remove the ripple and obtain a stable frequency. If CF is being used to measure energy, for example, in a microprocessor-based application, the CF output should also be averaged to calculate power. Because the outputs F1 and F2 operate at a much lower frequency, significant averaging of the instantaneous active power signal is carried out. The result is a greatly attenuated sinusoidal content and a virtually ripple-free frequency output on F1 and F2, which are used to measure energy in a stepper motor-based meter.

![Figure 23. Active Power-to-Frequency Conversion](image-url)
ACCUMULATION OF 3-PHASE POWER

Power Measurement Considerations

Calculating and displaying power information always have some associated ripple that depends on the integration period used in the MCU to determine average power as well as the load. For example, at light loads, the output frequency can be 10 Hz. With an integration period of 2 seconds, only about 20 pulses are counted. The possibility of missing one pulse always exists because the ADE7752B output frequency is running asynchronously to the MCU timer. This results in a 1-in-20 or 5% error in the power measurement. To remedy this, an appropriate integration time should be considered to achieve the desired accuracy.

Mode Selection of the Sum of the Three Active Energies

The ADE7752B can be configured to execute the arithmetic sum of the three active energies, \( Wh = WhΦA + WhΦB + WhΦC \), or the sum of the absolute value of these energies, \( Wh = |WhΦA| + |WhΦB| + |WhΦC| \). The selection between the two modes can be made by setting the ABS pin. Logic high and logic low applied on the ABS pin correspond to the arithmetic sum and the sum of absolute values, respectively.

When the sum of the absolute values is selected, the active energy from each phase is always counted positive in the total active energy. It is particularly useful in 3-phase, 4-wire installation where the sign of the active power should always be the same. If the meter is misconnected to the power lines, that is, if CT is connected in the wrong direction, the total active energy recorded without this solution can be reduced by two-thirds.

The sum of the absolute values assures that the active energy recorded represents the actual active energy delivered. In this mode, the reverse power pin still detects when the arithmetic sum of the active powers is negative, but energy continues to accumulate regardless of the sign.

Negative Total Power Detection

The ADE7752B detects when total power, calculated as the arithmetic sum of the three phases, is negative. This detection is independent of the mode of sum of the three powers (arithmetic or absolute). This mechanism can detect an incorrect connection of the meter or generation of negative active energy. When the sum of the powers of the three phases is negative, the REVP pin output goes active high. When the sum of the powers of the three phases is positive, the REVP pin output is reset to low.

The REVP pin output changes state at the same time as a pulse is issued on CF. If the sum of the powers of the three phases is negative, then the REVP pin output stays high until the sum is positive or all three phases are below the no-load threshold.
TRANSFER FUNCTION
FREQUENCY OUTPUTS F1 AND F2
The ADE7752B calculates the product of six voltage signals (on current channel and voltage channel) and then low-pass filters this product to extract active power information. This active power information is then converted to a frequency. The frequency information is output on F1 and F2 in the form of active high pulses. The pulse rate at these outputs is relatively low, for example, 2.09 Hz maximum for ac signals with SCF = S0 = 0; S1 = 1 (see Table 6). This means that the frequency at these outputs is generated from active power information accumulated over a relatively long period. The result is an output frequency that is proportional to the average active power. The averaging of the active power signal is implicit to the digital-to-frequency conversion. The output frequency or pulse rate is related to the input voltage signals by the following equation:

\[
Freq = \frac{6.181 \times \left( V_{AN} \times I_A + V_{BN} \times I_B + V_{CN} \times I_C \right)}{V_{REF}^2} \times f_{1 to 7} \tag{12}
\]

where:
- \( Freq \) is the output frequency on F1 and F2 (Hz).
- \( V_{AN}, V_{BN}, \) and \( V_{CN} \) are the differential rms voltage signals on voltage channels (V).
- \( I_A, I_B, \) and \( I_C \) are the differential rms voltage signals on current channels (V).
- \( V_{REF} \) is the reference voltage (2.4 V ± 8%) (V).
- \( f_{1 to 7} \) is one of seven possible frequencies selected by using the logic inputs SCF, S0, and S1 (see Table 5).

**Example 1**
In this example, with ac voltages of ±500 mV peak applied to the voltage channels and current channels, the expected output frequency is calculated as follows:

\[
f_{1 to 7} = 0.56 \text{ Hz}, \ SCF = S0 = S1 = 1
\]
\[
V_{AN} = V_{BN} = V_{CN} = I_A = I_B = I_C
\]
\[
= 500 \text{ mV peak ac} = \frac{0.5}{\sqrt{2}} \text{ V rms}
\]
\[
V_{REF} = 2.4 \text{ V (nominal reference value)}
\]

Note that if the on-chip reference is used, actual output frequencies can vary from device to device due to reference tolerance of ±8%.

\[
Freq = 3 \times \frac{6.313 \times 0.5 \times 0.5 \times 0.58}{\sqrt{2} \times \sqrt{2} \times 2.4^2} = 0.230 \text{ Hz} \tag{14}
\]

As can be seen from these two example calculations, the maximum output frequency for ac inputs is always half of that for dc input signals. The maximum frequency also depends on the number of phases connected to the ADE7752B. In a 3-phase, 3-wire delta service, the maximum output frequency is different from the maximum output frequency in a 3-phase, 4-wire Wye service. The reason is that there are only two phases connected to the analog inputs, but also that in a delta service, the current channel input and voltage channel input of the same phase are not in phase in normal operation.

\( f_{1 to 7} \) is a fraction of the master clock and therefore varies if the specified CLKN frequency is altered.
Example 2

In this example, the ADE7752B is connected to a 3-phase, 3-wire delta service as shown in Figure 17. The total active energy calculation processed in the ADE7752B can be expressed as

\[ \text{Total Active Power} = (V_A - V_C) \times I_A + (V_B - V_C) \times I_B \]

where:

- \( V_A, V_B, \) and \( V_C \) represent the voltage on Phase A, Phase B, and Phase C, respectively.
- \( I_A \) and \( I_B \) represent the current on Phase A and Phase B, respectively.

With respect to the voltage and current inputs in Equation 7 and Equation 8, the total active power \( P \) is

\[
\begin{align*}
P &= (V_A - V_C) \times (I_A - I_A) + (V_B - V_C) \times (I_B - I_B) \\
&= \sqrt{2} \times V_A \times \cos(\omega t) - \sqrt{2} \times V_C \times \cos\left(\omega t + \frac{4\pi}{3}\right) \\
&\quad + \sqrt{2} \times I_A \times \cos(\omega t) + \sqrt{2} \times V_B \times \cos\left(\omega t + \frac{2\pi}{3}\right) - \sqrt{2} \times V_C \times \cos\left(\omega t + \frac{4\pi}{3}\right) \\
&\quad + \sqrt{2} \times I_B \times \cos\left(\omega t + \frac{2\pi}{3}\right)
\end{align*}
\]

(Equation 15)

For simplification, assume that \( \Phi_A = \Phi_B = \Phi_C = 0 \) and \( V_A = V_B = V_C = V \). The preceding equation becomes

\[
P = 2 \times V \times I_A \times \sin\left(\frac{\pi}{3}\right) \times \sin\left(\omega t + \frac{2\pi}{3}\right) \times \cos(\omega t) + \\
2 \times V \times I_B \times \sin\left(\pi \times \frac{\pi}{3}\right) \times \sin(\omega t + \pi) \times \cos\left(\omega t + \frac{2\pi}{3}\right)
\]

(Equation 16)

\( P \) then becomes

\[
P = V_{AN} \times I_A \times \left(\sin\left(\frac{2\pi}{3}\right) + \sin\left(2\omega t + \frac{2\pi}{3}\right)\right) + \\
V_{BN} \times I_B \times \left(\sin\left(\pi \times \frac{\pi}{3}\right) + \sin\left(2\omega t + \frac{\pi}{3}\right)\right)
\]

(Equation 17)

where:

- \( V_{AN} = V \times \sin(2\pi/3) \)
- \( V_{BN} = V \times \sin(\pi/3) \)

As the LPF on each channel eliminates the \( 2\omega \) component of the equation, the active power measured by the ADE7752B is

\[
P = V_{AN} \times I_A \times \frac{\sqrt{3}}{2} + V_{BN} \times I_B \times \frac{\sqrt{3}}{2}
\]

(Equation 18)

If full-scale ac voltage of \( \pm 500 \text{ mV} \) peak is applied to the voltage channels and current channels, the expected output frequency is calculated as follows:

\[
f_{\text{ref}} = 0.56 \text{ Hz}, SCF = S0 = S1 = 1
\]

\[
V_{AN} = V_{BN} = I_A = I_B = I_C = 500 \text{ mV peak ac} = \frac{0.5}{\sqrt{2}} \text{ V rms}
\]

- \( V_{CN} = I_C = 0 \)
- \( V_{REF} = 2.4 \text{ V} \) nominal reference value

Note that if the on-chip reference is used, actual output frequencies can vary from device to device due to a reference tolerance of \( \pm 8\% \).

\[
Freq = 2 \times \frac{6.313 \times 0.5 \times 0.5 \times 0.56}{\sqrt{2} \times \sqrt{2} \times 2.4^2} \times \frac{\sqrt{3}}{2} = 0.133 \text{ Hz}
\]

(Equation 20)

Table 6 shows a complete listing of all maximum output frequencies when using all three channel inputs.

**FREQUENCY OUTPUT CF**

The pulse output calibration frequency (CF) is intended for use during calibration. The output pulse rate on CF can be up to \( 64\times \) the pulse rate on F1 and F2. Table 7 shows how the two frequencies are related, depending on the states of the logic inputs S0, S1, and SCF. Because of its relatively high pulse rate, the frequency at this logic output is proportional to the instantaneous active power. As is the case with F1 and F2, the frequency is derived from the output of the low-pass filter after multiplication. However, because the output frequency is high, this active power information is accumulated over a much shorter time. Thus, less averaging is carried out in the digital-to-frequency conversion. The CF output is much more responsive to power fluctuations with much less averaging of the active power signal (see Figure 11).

Table 7. Maximum Output Frequency on CF
SELECTING A FREQUENCY FOR AN ENERGY METER APPLICATION

As shown in Table 5, the user can select one of seven frequencies. This frequency selection determines the maximum frequency on F1 and F2. These outputs are intended to be used to drive the energy register (electromechanical or other). Because seven different output frequencies can be selected, the available frequency selection has been optimized for a 3-phase, 4-wire service with a meter constant of 100 imp/kWhr and a maximum current of between 10 A and 100 A. Table 8 shows the output frequency for several maximum currents (I\text{MAX}) with a line voltage of 220 V (phase neutral). In all cases, the meter constant is 100 imp/kWhr.

The f_1 to 7 frequencies allow complete coverage of this range of output frequencies on F1 and F2. When designing an energy meter, the nominal design voltage on the voltage channels should be set to half scale to allow for calibration of the meter constant. The current channel should also be no more than half scale when the meter sees maximum load. This allows overcurrent signals and signals with high crest factors to be accommodated. Table 9 shows the output frequency on F1 and F2 when all six analog inputs are half scale.

</table>

When selecting a suitable f_1 to 7 frequency for a meter design, the frequency output at I\text{MAX} (maximum load) with a 100 imp/kWhr meter constant should be compared with Column 5 of Table 9. The frequency that is closest in Table 9 determines the best choice of frequency (f_1 to 7). For example, if a 3-phase, 4-wire Wye meter with a 25 A maximum current is being designed, the output frequency on F1 and F2 with a 100 imp/kWhr meter constant is 0.46 Hz at 25 A and 220 V (see Table 8). Looking at Table 9, the closest frequency to 0.46 Hz in Column 5 is 0.46 Hz. Therefore, f_1 to 7 = 4.49 Hz is selected for this design.

FREQUENCY OUTPUTS

Figure 2 shows a timing diagram for the various frequency outputs. The outputs F1 and F2 are the low frequency outputs that can be used to directly drive a stepper motor or electromechanical impulse counter. The F1 and F2 outputs provide two alternating high going pulses. The pulse width (t_1) is set at 120 ms, and the time between the rising edges of F1 and F2 (t_3) is approximately half the period of F1 (t_2). If, however, the period of F1 and F2 falls below 550 ms (1.81 Hz), the pulse width of F1 and F2 is set to half of their period. The maximum output frequencies for F1 and F2 are shown in Table 6.

The high frequency CF output is intended to be used for communications and calibration purposes. CF produces a 90 ms-wide active high pulse (t_4) at a frequency proportional to active power. The CF output frequencies are given in Table 7. As in the case of F1 and F2, if the period of CF (t_5) falls below 190 ms, the CF pulse width is set to half the period. For example, if the CF frequency is 20 Hz, the CF pulse width is 25 ms.
NO-LOAD THRESHOLD

The ADE7752B includes an innovative no-load threshold detection scheme that detects if a current input, when multiplied with any of the three voltages inputs, cannot create power larger than a no-load threshold. This threshold represents 0.0075% of the full-scale output frequency.

For example, if the A, B and C voltage phases are 50% of full-scale input and 120° apart, and Current Phase A is 10% of full scale with a PF = 0, this detection scheme detects that \( V_A \times I_A \) is below the no-load threshold but that \( V_B \times I_A \) and \( V_C \times I_A \) are not. Therefore, the ADE7752B does not detect a no-load threshold for \( V_A \times I_A \), and lets this phase contribute to the total power. However, in the same voltage conditions, if current Phase A is 0.0075% of full scale with a PF = 1, this detection scheme detects that \( V_A \times I_A \) is below the no-load threshold and because \( V_B \times I_A \) and \( V_C \times I_A \) are as well, \( V_A \times I_A \) is detected as below the no-load threshold and its contribution to the total power is stopped.

The no-load threshold is given as 0.0075% of the full-scale output frequency for each of the \( f_1 \) to \( f_7 \) frequencies (see Table 10). For example, for an energy meter with a 100 imp/kWhr meter constant using \( f_1 \) to \( f_7 \) (4.49 Hz), the minimum output frequency at \( F_1 \) or \( F_2 \) is \( 1.38 \times 10^{-4} \) Hz. This is \( 2.21 \times 10^{-3} \) Hz at \( CF \) (16 × \( F_1 \) Hz). In this example, the no-load threshold is equivalent to 4.8 W of load, or a start-up current of 20.7 mA at 240 V.
