Energy Metering IC
with On-Chip Fault Detection
AD7751*

FEATURES
High Accuracy, Supports 50 Hz/60 Hz IEC 521/1036
Less than 0.1% Error Over a Dynamic Range of 500 to 1
The AD7751 Supplies Average Real Power On the
Frequency Outputs F1 and F2
The High Frequency Output CF Is Intended for Calibra-
tion and Supplies Instantaneous Real Power Data
Continuous Monitoring of the Phase and Neutral Current
Allows Fault Detection in Two-Wire Distribution Systems
The AD7751 Uses the Larger of the Two Currents (Phase
or Neutral) to Bill—Even During a Fault Condition
Two Logic Outputs (FAULT and REV) Can Be Used to
Indicate a Potential Miswiring or Fault Condition
Direct Drive for Electromechanical Counters and
Two-Phase Stepper Motors (F1 and F2)
A PGA in the Current Channel Allows the Use of Small
Values of Shunt and Burden Resistance
Proprietary ADCs and DSP Provide High Accuracy Over
Large Variations in Environmental Conditions and Time
On-Chip Power Supply Monitoring
On-Chip Creep Protection (No Load Threshold)
On-Chip Reference 2.5 V ± 8% (30 ppm/°C Typical)
with External Overdrive Capability
Single 5 V Supply, Low Power (15 mW Typical)
Low Cost CMOS Process

GENERAL DESCRIPTION
The AD7751 is a high accuracy fault tolerant electrical energy
measurement IC intended for use with two-wire distribution
systems. The part specifications surpass the accuracy require-
ments as quoted in the IEC1036 standard.

The only analog circuitry used on the AD7751 is in the ADCs
and reference circuit. All other signal processing (e.g., multipli-
cation and filtering) is carried out in the digital domain. This
approach provides superior stability and accuracy over extremes
in environmental conditions and over time.

The AD7751 incorporates a novel fault detection scheme that
both warns of fault conditions and allows the AD7751 to con-
tinue accurate billing during a fault event. The AD7751 does
this by continuously monitoring both the phase and neutral
(return) currents. A fault is indicated when these currents
differ by more than 12.5%. Billing is continued using the larger
of the two currents when the difference is greater than 14%.

The AD7751 supplies average real power information on the
low frequency outputs F1 and F2. These logic outputs may be
used to directly drive an electromechanical counter or interface
to an MCU. The CF logic output gives instantaneous real
power information. This output is intended to be used for cali-
bration purposes.

The AD7751 includes a power supply monitoring circuit on the
AVDD supply pin. The AD7751 will remain in a reset condition
until the supply voltage on AVDD reaches 4 V. If the supply falls
below 4 V, the AD7751 will also be reset and no pulses will be
issues on F1, F2 and CF.

Internal phase matching circuitry ensures that the voltage and
current channels are matched whether the HPF in Channel 1
is on or off. An internal no-load threshold ensures that the
AD7751 does not exhibit any creep when there is no load.

The AD7751 is available in 24-lead DIP and SSOP packages.

*Protected by U.S. Patent Nos. 5,745,323; 5,760,617; 5,862,069 and
5,872,469.

REV. 0

- Operating Temperature Range
  - Industrial (A, B Versions) ................. –40°C to +85°C
  - Storage Temperature Range ...................... –65°C to +150°C
  - Junction Temperature ......................... 150°C

**CAUTION**

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the AD7751 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

**TERMINOLOGY**

**MEASUREMENT ERROR**

The error associated with the energy measurement made by the AD7751 is defined by the following formula:

\[
\text{Percentage Error} = \frac{\text{Energy Registered by the AD7751} - \text{True Energy}}{\text{True Energy}} \times 100\%
\]

**PHASE ERROR BETWEEN CHANNELS**

The HPF (High Pass Filter) in Channel 1 has a phase lead response. To offset this phase response and equalize the phase response between channels a phase correction network is also placed in Channel 1. The phase correction network matches the phase to within ±0.1° over a range of 45 Hz to 65 Hz and ±0.2° over a range 40 Hz to 1 kHz.

**POWER SUPPLY REJECTION**

This quantifies the AD7751 measurement error as a percentage of reading when the power supplies are varied.

For the ac PSR measurement a reading at nominal supplies (5 V) is taken. A 200 mV rms/100 Hz signal is then introduced onto the supplies and a second reading obtained under the same input signal levels. Any error introduced is expressed as a percentage of reading—see Measurement Error definition.

For the dc PSR measurement a reading at nominal supplies (5 V) is taken. The supplies are then varied ±5% and a second reading is obtained with the same input signal levels. Any error introduced is again expressed as a percentage of reading.

**ADC OFFSET ERROR**

This refers to the dc offset associated with the analog inputs to the ADCs. It means that with the analog inputs connected to AGND the ADCs still see an analog input signal of 0 mV to ±15 mV, depending on gain setting. However, when the HPF is switched on the offset is removed from the current channel and the power calculation is not affected by this offset.

**GAIN ERROR**

The gain error of the AD7751 is defined as the difference between the measured output frequency (minus the offset) and the ideal output frequency. It is measured with a gain of 1 in Channel 1. The difference is expressed as a percentage of the ideal frequency. The ideal frequency is obtained from the transfer function—see Transfer Function section.

**GAIN ERROR MATCH**

The gain error match is defined as the gain error (minus the offset) obtained when switching between a gain of 1 and a gain of 2, 8, or 16. It is expressed as a percentage of the output frequency obtained under a gain of 1. This gives the gain error observed when the gain selection is changed from 1 to 2, 8 or 16.
## PIN FUNCTION DESCRIPTIONS

<table>

</table>

### PIN CONFIGURATION

**DIP and SSOP Packages**

![PIN CONFIGURATION Diagram](image-url)
THEORY OF OPERATION
The ADCs digitize the voltage signals from the current and voltage transducers. These ADCs are 16-bit second order sigma-delta with an oversampling rate of 900 kHz. This analog input structure greatly simplifies transducer interfacing by providing a wide dynamic range for direct connection to the transducer and also simplifying the antialiasing filter design. A programmable gain stage in the current channel further facilitates easy transducer interfacing. A high-pass filter in the current channel removes any dc component from the current signal. This eliminates any inaccuracies in the real power calculation due to offsets in the voltage or current signals—see HPF and Offset Effects section.

The real power calculation is derived from the instantaneous power signal. The instantaneous power signal is generated by a direct multiplication of the current and voltage signals. In order to extract the real power component (i.e., the dc component) the instantaneous power signal is low-pass filtered. Figure 2 illustrates the instantaneous real power signal and shows how the real power information can be extracted by low-pass filtering the instantaneous power signal. This scheme correctly calculates real power for nonsinusoidal current and voltage waveforms at all power factors. All signal processing is carried out in the digital domain for superior stability over temperature and time.

The low frequency output of the AD7751 is generated by accumulating this real power information. This low frequency inherently means a long accumulation time between output pulses. The output frequency is therefore proportional to the average real power. This average real power information can in turn be accumulated (e.g., by a counter) to generate real energy information. Because of its high output frequency and hence shorter integration time, the CF output is proportional to the instantaneous real power. This is useful for system calibration purposes that would take place under steady load conditions.

Power Factor Considerations
The method used to extract the real power information from the instantaneous power signal (i.e., by low-pass filtering) is still valid even when the voltage and current signals are not in phase. Figure 3 below displays the unity power factor condition and a DPF (Displacement Power Factor) = 0.5, i.e., current signal lagging the voltage by 60°. If we assume the voltage and current waveforms are sinusoidal, the real power component of the instantaneous power signal (i.e., the dc term) is given by \((V.I/2) \times \cos(0°)\). This is the correct real power calculation.

Nonsinusoidal Voltage and Current
The real power calculation method also holds true for nonsinusoidal current and voltage waveforms. All voltage and current waveforms in practical applications will have some harmonic content. Using the Fourier Transform, instantaneous voltage and current waveforms can be expressed in terms of their harmonic content.

\[
v(t) = V_O + \sqrt{2} \times \sum_{h=0}^{\infty} V_h \times \sin(h\omega t + \alpha_h)
\]

where:
- \(v(t)\) is the instantaneous voltage
- \(V_O\) is the average value
- \(V_h\) is the rms value of voltage harmonic \(h\)
- \(\alpha_h\) is the phase angle of the voltage harmonic.

\[
i(t) = I_O + \sqrt{2} \times \sum_{h=0}^{\infty} I_h \times \sin(h\omega t + \beta_h)
\]

where:
- \(i(t)\) is the instantaneous current
- \(I_O\) is the dc component
- \(I_h\) is the rms value of current harmonic \(h\)
- \(\beta_h\) is the phase angle of the current harmonic.

\[
\]
Using Equations 1 and 2, the real power $P$ can be expressed in terms of its fundamental real power ($P_1$) and harmonic real power ($P_H$).

$$P = P_1 + P_H$$

where:

$$P_1 = V_1 \times I_1 \cos \phi_1$$

$$\phi_1 = \alpha_1 - \beta_1$$

and

$$P_H = \sum_{h=1}^{\infty} V_h \times I_h \cos \phi_h$$

$$\phi_h = \alpha_h - \beta_h$$

As can be seen from Equation 4 above, a harmonic real power component is generated for every harmonic, provided that harmonic is present in both the voltage and current waveforms. The Power Factor calculation has previously been shown to be accurate in the case of a pure sinusoid, therefore the harmonic real power must also correctly account for Power Factor since it is made up of a series of pure sinusoids.

Note that the input bandwidth of the analog inputs is 14 kHz with a master clock frequency of 3.5795 MHz.

ANALOG INPUTS

Channel V2 (Voltage Channel)
The output of the line voltage transducer is connected to the AD7751 at this analog input. Channel V2 is a fully differential voltage input. The maximum peak differential signal on Channel 2 is ±660 mV. Figure 4 illustrates the maximum signal levels that can be connected to the AD7751 Channel 2.

The analog inputs V1A, V1B and V1N have the same maximum signal level restrictions as V2P and V2N. However, Channel 1
has a programmable gain amplifier (PGA) with user-selectable gains of 1, 2, 8 or 16—see Table I. These gains facilitate easy transducer interfacing.

As can be seen from Figure 5 above, a harmonic real power component is generated for every harmonic, provided that harmonic is present in both the voltage and current waveforms. The Power Factor calculation has previously been shown to be accurate in the case of a pure sinusoid, therefore the harmonic real power must also correctly account for Power Factor since it is made up of a series of pure sinusoids.

Note that the input bandwidth of the analog inputs is 14 kHz with a master clock frequency of 3.5795 MHz.

ANALOG INPUTS

Channel V2 (Voltage Channel)
The output of the line voltage transducer is connected to the AD7751 at this analog input. Channel V2 is a fully differential voltage input. The maximum peak differential signal on Channel 2 is ±660 mV. Figure 4 illustrates the maximum signal levels that can be connected to the AD7751 Channel 2.

The diagram in Figure 5 illustrates the maximum signal levels on V1A, V1B and V1N. The maximum differential voltage is ±660 mV divided by the gain selection. Again the differential voltage signal on the inputs must be referenced to a common mode, e.g., AGND.

Typical Connection Diagrams

Figure 6 shows a typical connection diagram for Channel V1. Here the analog inputs are being used to monitor both the Phase and Neutral currents. Because of the large potential difference between the phase and neutral, two CTs (current transformers) must be used to provide the isolation. Notice both CTs are referenced to AGND (analog ground), hence the common-mode voltage is 0 V. The CT turns ratio and burden resistor (Rb) are selected to give a peak differential voltage of ±660 mV/Gain.
Figure 7 shows two typical connections for Channel V2. The first option uses a PT (potential transformer) to provide complete isolation from the mains voltage. In the second option the AD7751 is biased around the neutral wire and a resistor divider is used to provide a voltage signal that is proportional to the line voltage. Adjusting the ratio of Ra and Rb is also a convenient way of carrying out a gain calibration on the meter.

**POWER SUPPLY MONITOR**

The AD7751 contains an on-chip power supply monitor. The analog supply (AVDD) is continuously monitored by the AD7751. If the supply is less than 4 V ± 5%, the AD7751 will be reset. This is useful to ensure correct device start-up at power-up and power-down. The power supply monitor has built in hysteresis and filtering. This gives a high degree of immunity to false triggering due to noisy supplies.

**HPF and Offset Effects**

Figure 9 shows the effect of offsets on the real power calculation. As can be seen from Figure 9 an offset on Channel 1 and Channel 2 will contribute a dc component after multiplication. Since this dc component is extracted by the LPF and used to generate the real power information, the offsets will have contributed a constant error to the real power calculation. This problem is easily avoided by enabling the HPF (i.e., pin AC/DC is set logic high) in Channel 1. By removing the offset from at least 1 channel no error component can be generated at dc by the multiplication. Error terms at $\cos(\omega t)$ are removed by the LPF and the Digital-to-frequency conversion—see Digital-to-Frequency Conversion section.

$$\left\{ V \cos(\omega t) + V_{OS} \right\} \times \left\{ I \cos(\omega t) + I_{OS} \right\} =$$

$$\frac{V \times I}{2} + V_{OS} \times I_{OS} + V_{OS} \times I \cos(\omega t) + I_{OS} \times V \cos(\omega t)$$

**Figure 8. On-Chip Power Supply Monitor**

As can be seen from Figure 8 the trigger level is nominally set at 4 V. The tolerance on this trigger level is about ±5%. The power supply and decoupling for the part should be such that the ripple at AVDD does not exceed 5 V ± 5% as specified for normal operation.
DIGITAL-TO-FREQUENCY CONVERSION.

As previously described the digital output of the low-pass filter after multiplication contains the real power information. However since this LPF is not an ideal “brick wall” filter implementation, the output signal also contains attenuated components at the line frequency and its harmonics, i.e., \( \cos(h \cdot \omega \cdot t) \) where \( h = 1, 2, 3, \ldots \) etc. The magnitude response of the filter is given by:

\[
| H(f) | = \frac{1}{1 + (f / 8.9 \text{ Hz})} \quad (5)
\]

For a line frequency of 50 Hz, this would give an attenuation of the \( 2\omega \) (100 Hz) component of approximately –22 dBs. The dominating harmonic will be at twice the line frequency, i.e., \( \cos(2\omega t) \) and this is due to the instantaneous real power signal.

Figure 10 shows the instantaneous real power signal output of LPF which still contains a significant amount of instantaneous power information, i.e., \( \cos(2\omega t) \). This signal is then passed to the digital-to-frequency converter where it is integrated (accumulated) over time in order to produce an output frequency. This accumulation of the signal will suppress or average out any non-dc components in the instantaneous real power signal. The average value of a sinusoidal signal is zero. Hence the frequency generated by the AD7751 is proportional to the average real power. Figure 12 below shows the digital-to-frequency conversion for steady load conditions, i.e., constant voltage and current.

Figure 11 shows the instantaneous real power signal output of LPF which still contains a significant amount of instantaneous power information, i.e., \( \cos(2\omega t) \). This signal is then passed to the digital-to-frequency converter where it is integrated (accumulated) over time in order to produce an output frequency. This accumulation of the signal will suppress or average out any non-dc components in the instantaneous real power signal. The average value of a sinusoidal signal is zero. Hence the frequency generated by the AD7751 is proportional to the average real power. Figure 12 below shows the digital-to-frequency conversion for steady load conditions, i.e., constant voltage and current.
FAULT DETECTION
The AD7751 incorporates a novel fault detection scheme which both warns of fault conditions and allows the AD7751 to continue accurate billing during a fault event. The AD7751 does this by continuously monitoring both the phase and neutral (return) currents. A fault is indicated when these currents differ by more than 12.5%. However, even during a fault the output pulse rate on F1 and F2 is generated using the larger of the two currents. Because the AD7751 looks for a difference between the voltage signals on V1A and V1B, it is important that both current transducers are closely matched.

On power-up the output pulse rate of the AD7751 is proportional to the product of the voltage signals on V1A and Channel 2. If there is a difference of greater than 12.5% between V1A and V1B on power-up, the fault indicator (FAULT) will go active after about one second. In addition, if V1B is greater than V1A the AD7751 will select V1B as the input. The fault detection is automatically disabled when the voltage signal on Channel 1 is less than 0.3% of the full-scale input range. This will eliminate false detection of a fault due to noise at light loads.

Fault with Active Input Greater than Inactive Input
If V1A is the active current input (i.e., is being used for billing), and the voltage signal on V1B (inactive input) falls by more than 12.5% of V1A, the fault indicator will go active. Both analog inputs are filtered and averaged to prevent false triggering of this logic output. As a consequence of the filtering, there is a time delay of approximately one second on the logic output FAULT after the fault event. The FAULT logic output is independent of any activity on outputs F1 or F2. Figure 13 below illustrates one condition under which FAULT becomes active. Since V1A is the active input and it is still greater than V1B, billing is maintained on V1A, i.e., no swap to the V1B input will occur. V1A remains the active input.

Fault with V1B Greater than V1A
Figure 14 illustrates another fault condition. If V1A is the active input (i.e., is being used for billing), and the voltage signal on V1B (inactive input) becomes greater than 114% of V1A, the FAULT indicator goes active and there is also a swap over to the V1B input. The analog input V1B has now become the active input. Again there is a time constant of about 1 second associated with this swap. V1A will not swap back to being the active channel until V1A becomes greater than 114% of V1B. However the FAULT indicator will become inactive as soon as V1A is within 12.5% of V1B. This threshold eliminates potential chatter between V1A and V1B.

Calibration Concerns
Typically, when a meter is being calibrated, the voltage and current circuits are separated as shown in Figure 15. This means that current will only pass through the phase or neutral circuit. Figure 15 shows current being passed through the phase circuit. This is the preferred option since the AD7751 starts billing on the input V1A on power-up. The phase circuit CT is connected to V1A in the diagram. Since there is no current in the Neutral circuit the FAULT indicator will come on under these conditions. However, this does not affect the accuracy of the calibration and can be used as a means to test the functionality of the fault detection.

If the neutral circuit is chosen for the current circuit in the arrangement shown in Figure 15 this may have implications for the calibration accuracy. The AD7751 will power-up with the V1A input active as normal. However, since there is no current in the phase circuit the signal on V1A is zero. This will cause a FAULT to be flagged and the active input to be swapped to V1B (Neutral). The meter may be calibrated in this mode but the phase and neutral CTs may differ slightly. Since under no-fault conditions all billing is carried out using the phase CT, the meter should be calibrated using the phase circuit. Of course, both phase and neutral circuits may be calibrated.
TRANSFER FUNCTION

Frequency Outputs F1 and F2
The AD7751 calculates the product of two voltage signals (on Channel 1 and Channel 2) and then low-pass filters this product to extract real power information. This real power information is then converted to a frequency. The frequency information is output on F1 and F2 in the form of active low pulses. The pulse rate at these outputs is relatively low, e.g., 0.34 Hz maximum for ac signals with \( S_0 = S_1 = 0 \)—see Table III. This means that the frequency at these outputs is generated from real power information accumulated over a relatively long period of time. The result is an output frequency that is proportional to the average real power. The averaging of the real power signal is implicit to the digital-to-frequency conversion. The output frequency or pulse rate is related to the input voltage signals by the following equation.

\[
Freq = \frac{5.74 \times V_1 \times V_2 \times Gain \times F_{1-4}}{V_{REF}^2}
\]

where,

- \( Freq \) = Output frequency on F1 and F2 (Hz)
- \( V_1 \) = Differential rms voltage signal on Channel 1 (volts)
- \( V_2 \) = Differential rms voltage signal on Channel 2 (volts)
- \( Gain \) = 1, 2, 8 or 16, depending on the PGA gain selection made using logic inputs \( G_0 \) and \( G_1 \)
- \( V_{REF} \) = The reference voltage (2.5 V \( \pm 8\% \)) (volts)
- \( F_{1-4} \) = One of four possible frequencies selected by using the logic inputs \( S_0 \) and \( S_1 \) — see Table II

Table II. F1-4 Frequency Selection

</tr>
</tbody>
</table>

NOTE: \( F_{1-4} \) are a binary fraction of the master clock and will thus vary if the specified CLKIN frequency is altered.

Example 1
If full-scale differential dc voltages of +660 mV and –660 mV are applied to V1 and V2 respectively (660 mV is the maximum differential voltage which can be connected to Channel 1 and Channel 2), the expected output frequency is calculated as follows.

\[
Gain = 1, G_0 = G_1 = 0
\]

\[
F_{1-4} = 1.7 \text{ Hz}, S_0 = S_1 = 0
\]

\[
V_1 = \text{rms of 660 mV peak ac} = 0.66/\sqrt{2} \text{ volts}
\]

\[
V_2 = \text{rms of 660 mV peak ac} = 0.66/\sqrt{2} \text{ volts}
\]

\[
V_{REF} = 2.5 \text{ V (nominal reference value)}.
\]

Example 2
In this example, if ac voltages of \( \pm 660 \text{ mV} \) peak are applied to V1 and V2 then the expected output frequency is calculated as follows.

\[
Gain = 1, G_0 = G_1 = 0
\]

\[
F_{1-4} = 1.7 \text{ Hz}, S_0 = S_1 = 0
\]

\[
V_1 = \text{rms of 660 mV peak ac} = 0.66/\sqrt{2} \text{ volts}
\]

\[
V_2 = \text{rms of 660 mV peak ac} = 0.66/\sqrt{2} \text{ volts}
\]

\[
V_{REF} = 2.5 \text{ V (nominal reference value)}.
\]

NOTE: If the on-chip reference is used, actual output frequencies may vary from device to device due to reference tolerance of \( \pm 8\% \).

\[
Freq = \frac{5.74 \times 0.66 \times 0.66 \times 1 \times 1.7 \text{ Hz}}{\sqrt{2} \times \sqrt{2} \times 2.5^2} = 0.34 \text{ Hz}
\]

As can be seen from these two example calculations the maximum output frequency for ac inputs is always half of that for dc input signals. Table III shows a complete listing of all maximum output frequencies.

Frequency Output CF
The pulse output CF (Calibration Frequency) is intended for use during calibration. The output pulse rate on CF can be up to 128 times the pulse rate on F1 and F2. The lower the \( F_{1-4} \) frequency selected the higher the CF scaling. Table IV shows how the two frequencies are related depending on the states of the logic inputs \( S_0, S_1 \) and \( SCF \). Because of its relatively high pulse rate, the frequency at this logic output is proportional to the instantaneous real power. As is the case with F1 and F2, the frequency is derived from the output of the low-pass filter after multiplication. However, because the output frequency is high, this real power information is accumulated over a much shorter time. Hence less averaging is carried out in the digital-to-frequency conversion. With much less averaging of the real power signal, the CF output is much more responsive to power fluctuations — see Signal Processing Block in Figure 2.

SELECTION A FREQUENCY FOR AN ENERGY METER APPLICATION

As shown in Table II the user can select one of four frequencies. This frequency selection determines the maximum frequency on F1 and F2. These outputs are intended to be used to drive the energy register (electromechanical or other). Since only four different output frequencies can be selected, the available frequency selection has been optimized for a meter constant of 100 imp/kWhr with a maximum current of between 10 A and 120 A. Table V shows the output frequency for several maximum currents (I_max) with a line voltage of 220 V. In all cases the meter constant is 100 imp/kWhr.

The F1–4 frequencies allow complete coverage of this range of output frequencies on F1 and F2. When designing an energy meter the nominal design voltage on Channel 2 (voltage) should be set to half-scale to allow for calibration of the meter constant. The current channel should also be no more than half-scale when the meter sees maximum load. This will allow over current signals and signals with high crest factors to be accommodated. Table VI shows the output frequency on F1 and F2 when both analog inputs are half-scale. The frequencies listed in Table VI align very well with those listed in Table V for maximum load.

</table>

When selecting a suitable F1–4 frequency for a meter design the frequency output at I_max (maximum load) with a meter constant of 100 imp/kWhr should be compared with Column 4 of Table VI. The frequency which is closest in Table VI will determine the best choice of frequency (F1–4). For example if a meter with a maximum current of 25 A is being designed the output frequency on F1 and F2 with a meter constant of 100 imp/kWhr is 0.153 Hz at 25 A and 220 V (from Table V). Looking at Table VI the closest frequency to 0.153 Hz in column four is 0.17 Hz. Therefore F2 (3.4 Hz—see Table II) is selected for this design.

Frequency Outputs

Figure 1 shows a timing diagram for the various frequency outputs. The outputs F1 and F2 are the low frequency outputs that can be used to directly drive a stepper motor or electromechanical impulse counter. The F1 and F2 outputs provide two alternating low going pulses. The pulsewidth (t1) is set at 275 ms and the time between the falling edges of F1 and F2 (t3) is approximately half the period of F1 (t2). If, however, the period of F1 and F2 falls below 550 ms (1.81 Hz), the pulsewidth of F1 and F2 is set to half of their period. The maximum output frequencies for F1 and F2 are shown in Table III.

The high frequency CF output is intended to be used for communications and calibration purposes. CF produces a 90-ms-wide active high pulse (t4) at a frequency that is proportional to active power. The CF output frequencies are given in Table IV. As in the case of F1 and F2, if the period of CF (t5) falls below 180 ms, the CF pulsewidth is set to half the period. For example, if the CF frequency is 20 Hz the CF pulsewidth is 25 ms.

NO LOAD THRESHOLD

The AD7751 also includes a “no load threshold” and “start-up current” feature that will eliminate any creep effects in the meter. The AD7751 is designed to issue a minimum output frequency. Any load generating a frequency lower than this minimum frequency will not cause a pulse to be issued on F1, F2 or CF. The minimum output frequency is given as 0.0014% of the full scale output frequency for each of the F1–4 frequency selections—see Table II. For example, an energy meter with a meter constant of 100 imp/kWhr on F1, F2 using F2 (3.4 Hz), the maximum output frequency at F1 or F2 would be 0.0014% of 3.4 Hz or 4.76 x 10^-5 Hz. This would be 3.05 x 10^-3 Hz at CF (64 x F1 Hz). In this example the no load threshold would be equivalent to 1.7 W of load or a start-up current of 8 mA at 220 V. Compare this value to the IEC1036 specification, which states that the meter must start up with a load equal to or less than 0.4% Ib. For a 5 A(Ib) meter 0.4% of Ib is equivalent to 20 mA.
