**LTC1625**  
**No RSENSE™ Current Mode Synchronous Step-Down Switching Regulator**

**FEATURES**
- Highest Efficiency Current Mode Controller
- No Sense Resistor Required
- Stable High Current Operation
- Dual N-Channel MOSFET Synchronous Drive
- Wide VIN Range: 3.7V to 36V
- Wide VOUT Range: 1.19V to VIN
- ±1% 1.19V Reference
- Programmable Fixed Frequency with Injection Lock
- Very Low Drop Out Operation: 99% Duty Cycle
- Forced Continuous Mode Control Pin
- Optional Programmable Soft Start
- Pin Selectable Output Voltage
- Foldback Current Limit
- Output Overvoltage Protection
- Logic Controlled Micropower Shutdown: IQ < 30µA
- Available in 16-Lead Narrow SSOP and SO Packages

**APPLICATIONS**
- Notebook and Palmtop Computers, PDAs
- Cellular Telephones and Wireless Modems
- Battery Chargers
- Distributed Power

**DESCRIPTION**

The LTC®1625 is a synchronous step-down switching regulator controller that drives external N-Channel power MOSFETs using few external components. Current mode control with MOSFET VDS sensing eliminates the need for a sense resistor and improves efficiency. The frequency of a nominal 150kHz internal oscillator can be synchronized to an external clock over a 1.5:1 frequency range.

Burst Mode™ operation at low load currents reduces switching losses and low dropout operation extends operating time in battery-powered systems. A forced continuous mode control pin can assist secondary winding regulation by disabling Burst Mode operation when the main output is lightly loaded.

Fault protection is provided by foldback current limiting and an output overvoltage comparator. An external capacitor attached to the RUN/SS pin provides soft start capability for supply sequencing. A wide supply range allows operation from 3.7V (3.9V for LTC1625I) to 36V at the input and 1.19V to VIN at the output.

**TYPICAL APPLICATION**

- Notebook and Palmtop Computers, PDAs
- Cellular Telephones and Wireless Modems
- Battery Chargers
- Distributed Power

**Note 1:** Absolute Maximum Ratings are those values beyond which the life of a device may be impaired.

**Note 2:** $T_J$ is calculated from the ambient temperature $T_A$ and power dissipation $P_D$ according to the following formula:

LTC1625CGN/LTC1625IGN: $T_J = T_A + (P_D \cdot 130^\circ C/W)$
LTC1625CS/LTC1625IS: $T_J = T_A + (P_D \cdot 110^\circ C/W)$

**Note 3:** The LTC1625 is tested in a feedback loop that adjusts $V_{SENSE}$ to achieve a specified error amplifier output voltage ($V_{TH}$).

**Note 4:** Typical in application circuit with $EXTVCC$ tied to $VOUT = 5V$, $IOUT = 0A$ and $FCB = INTVCC$. Dynamic supply current is higher due to the gate charge being delivered at the switching frequency. See Applications Information.

**Note 5:** Minimum input supply voltage is 3.9V at $-40^\circ C$ for industrial grade parts.

**PIN FUNCTIONS**

**EXTVCC (Pin 1):** INTVCC Switch Input. When the EXTVCC voltage is above 4.7V, the switch closes and supplies INTVCC power from EXTVCC. Do not exceed 7V at this pin.

**SYNC (Pin 2):** Synchronization Input for Internal Oscillator. The oscillator will nominally run at 150kHz when open, 225kHz when tied above 1.2V, and will lock over a 1.5:1 clock frequency range.

**RUN/SS (Pin 3):** Run Control and Soft Start Input. A capacitor to ground at this pin sets the ramp time to full current output (approximately 1s/μF). Forcing this pin below 1.4V shuts down the device.

**FCB (Pin 4):** Forced Continuous Input. Tie this pin to ground to force synchronous operation at low load, to a resistive divider from the secondary output when using a secondary winding, or to INTVCC to enable Burst Mode operation at low load.

**I_{TH} (Pin 5):** Error Amplifier Compensation Point. The current comparator threshold increases with this control voltage. Nominal voltage range for this pin is 0V to 2.4V.

**SGND (Pin 6):** Signal Ground. Connect to the (–) terminal of COUT.

**V_{SENSE} (Pin 7):** Output Voltage Sense. Feedback input from the remotely sensed output voltage or from an external resistive divider across the output.

**V_{PROG} (Pin 8):** Output Voltage Programming. When V_{SENSE} is connected to the output, V_{PROG} < 0.8V selects a 3.3V output and V_{PROG} > 3.5V selects a 5V output. Leaving V_{PROG} open allows the output voltage to be set by an external resistive divider between the output and V_{SENSE}.

**PGND (Pin 9):** Driver Power Ground. Connects to the source of the bottom N-channel MOSFET, the (–) terminal of C_{VCC} and the (–) terminal of C_{IN}.

**BG (Pin 10):** Bottom Gate Drive. Drives the gate of the bottom N-channel MOSFET between ground and INTVCC.

**INTVCC (Pin 11):** Internal 5.2V Regulator Output. The driver and control circuits are powered from this voltage. Decouple this pin to power ground with a minimum of 4.7μF tantalum capacitance.

**BOOST (Pin 12):** Topside Floating Driver Supply. The (+) terminal of the bootstrap capacitor connects here. This pin swings from a diode drop below INTVCC to VIN + INTVCC.

**TG (Pin 13):** Top Gate Drive. Drives the top N-channel MOSFET with a voltage swing equal to INTVCC minus a diode drop, superimposed on the switch node voltage.

**SW (Pin 14):** Switch Node. The (–) terminal of the bootstrap capacitor connects here. This pin swings from a diode drop below ground up to VIN.

**TK (Pin 15):** Top MOSFET Kelvin Sense. MOSFET V_{DS} sensing requires this pin to be routed to the drain of the top MOSFET separately from VIN.

**VIN (Pin 16):** Main Supply Input. Decouple this pin to ground with an RC filter (4.7Ω, 0.1μF) for applications above 3A.
**OPERATION**

**Main Control Loop**

The LTC1625 is a constant frequency, current mode controller for DC/DC step-down converters. In normal operation, the top MOSFET is turned on when the RS latch is set by the on-chip oscillator and is turned off when the current comparator I₁ resets the latch. While the top MOSFET is turned off, the bottom MOSFET is turned on until either the inductor current reverses, as determined by the current reversal comparator I₂, or the next cycle begins. Inductor current is measured by sensing the VDS potential across the conducting MOSFET. The output of the appropriate sense amplifier (TA or BA) is selected by the switch logic and applied to the current comparator. The voltage on the I₈ pin sets the comparator threshold corresponding to peak inductor current. The error amplifier EA adjusts this voltage by comparing the feedback signal VFB from the output voltage with the internal 1.19V reference. The Vprog pin selects whether the feedback voltage is taken directly from the VOSense pin or is derived from an on-chip resistive divider. When the load current increases, it causes a drop in the feedback voltage relative to the reference. The I₈ voltage then rises until the average inductor current again matches the load current.

The internal oscillator can be synchronized to an external clock applied to the SYNC pin and can lock to a frequency between 100% and 150% of its nominal 150kHz rate. When the SYNC pin is left open, it is pulled low internally and the oscillator runs at its normal rate. The I₈ voltage then rises until the average inductor current again matches the load current.

Pulling the RUN/SS pin low forces the controller into its shutdown state and turns off both MOSFETs. Releasing the RUN/SS pin allows an internal 3µA current source to charge up an external soft start capacitor Cₛₛ. When this voltage reaches 1.4V, the controller begins switching, but with the I₈ voltage clamped at approximately 0.8V. As Cₛₛ continues to charge, the clamp is raised until full range operation is restored.

The top MOSFET driver is powered from a floating bootstrap capacitor Cₜ. This capacitor is normally recharged from INTVCC through a diode DB when the top MOSFET is turned off. As VIN decreases towards VOUT, the converter will attempt to turn on the top MOSFET continuously ("dropout"). A dropout counter detects this condition and forces the top MOSFET to turn off for about 500ns every tenth cycle to recharge the bootstrap capacitor.

An overvoltage comparator OV guards against transient overshoots and other conditions that may overvoltage the output. In this case, the top MOSFET is turned off and the bottom MOSFET is turned on until the overvoltage condition is cleared.

Foldback current limiting for an output shorted to ground is provided by a transconductance amplifier CL. As VFB drops below 0.6V, the buffered I₈ input to the current comparator is gradually pulled down to a 0.95V clamp. This reduces peak inductor current to about one fifth of its maximum value.

**Low Current Operation**

The LTC1625 is capable of Burst Mode operation at low load currents. If the error amplifier drives the I₈ voltage below 0.95V, the buffered I₈ input to the current comparator will remain clamped at 0.95V. The inductor current peak is then held at approximately 30mV/RDS(ON)(TOP). If I₈ then drops below 0.5V, the Burst Mode comparator B will turn off both MOSFETs. The load current will be supplied solely by the output capacitor until I₈ rises above the 50mV hysteresis of the comparator and switching is resumed. Burst Mode operation is disabled by comparator F when the FCB pin is brought below 1.19V. This forces continuous operation and can assist secondary winding regulation.

**INTVCC/EXTVCC Power**

Power for the top and bottom MOSFET drivers and most of the internal circuitry of the LTC1625 is derived from the INTVCC pin. When the EXTVCC pin is left open, an internal 5.2V low dropout regulator supplies the INTVCC power from VIN. If EXTVCC is raised above 4.7V, the internal regulator is turned off and an internal switch connects EXTVCC to INTVCC. This allows a high efficiency source, such as the primary or a secondary output of the converter itself, to provide the INTVCC power.
The basic LTC1625 application circuit is shown in Figure 1. External component selection is primarily determined by the maximum load current and begins with the selection of the sense resistance and power MOSFETs. Because the LTC1625 uses MOSFET $V_{DS}$ sensing, the sense resistance is the $R_{DS(ON)}$ of the MOSFETs. The operating frequency and the inductor are chosen based largely on the desired amount of ripple current. Finally, $C_{IN}$ is selected for its ability to handle the large RMS current into the converter and $C_{OUT}$ is chosen with low enough ESR to meet the output voltage ripple specification.

### Power MOSFET Selection

The LTC1625 requires two external N-channel power MOSFETs, one for the top (main) switch and one for the bottom (synchronous) switch. Important parameters for the power MOSFETs are the breakdown voltage $V_{(BR)DSS}$, threshold voltage $V_{GS(TH)}$, on-resistance $R_{DS(ON)}$, reverse transfer capacitance $C_{RSS}$ and maximum current $I_{D(MAX)}$. The gate drive voltage is set by the 5.2V INTV$_{CC}$ supply. Consequently, logic level threshold MOSFETs must be used in LTC1625 applications. If low input voltage operation is expected ($V_{IN} < 5V$), then sub-logic level threshold MOSFETs should be used. Pay close attention to the $V_{(BR)DSS}$ specification for the MOSFETs as well; many of the logic level MOSFETs are limited to 30V or less.

The MOSFET on-resistance is chosen based on the required load current. The maximum average output current $I_{O(MAX)}$ is equal to the peak inductor current less half the peak-to-peak ripple current $\Delta I_L$. The peak inductor current is inherently limited in a current mode controller by the current threshold $I_{TH}$ range. The corresponding maximum $V_{DS}$ sense voltage is about 150mV under normal conditions. The LTC1625 will not allow peak inductor current to exceed 150mV/$R_{DS(ON)(TOP)}$. The following equation is a good guide for determining the required $R_{DS(ON)(MAX)}$ at 25°C (manufacturer’s specification), allowing some margin for ripple current, current limit and variations in the LTC1625 and external component values:

$$R_{DS(ON)(MAX)} \equiv \frac{120mV}{(I_{O(MAX)})(\rho_T)}$$

The $\rho_T$ is a normalized term accounting for the significant variation in $R_{DS(ON)}$ with temperature, typically about 0.4%/°C as shown in Figure 2. Junction to case temperature $T_{JC}$ is around 10°C in most applications. For a maximum ambient temperature of 70°C, using $\rho_{80°C} \equiv 1.3$ in the above equation is a reasonable choice. This equation is plotted in Figure 3 to illustrate the dependence of maximum output current on $R_{DS(ON)}$. Some popular MOSFETs from Siliconix are shown as data points.
The MOSFET power dissipations at maximum output current are:

\[
P_{\text{TOP}} = \left( \frac{V_{\text{OUT}}}{V_{\text{IN}}} \right) (I_{\text{O(MAX)}})^2 \left( \rho_{\text{TOP}} \right) (R_{\text{DS(ON)}}) \\
+ (k)(V_{\text{IN}})^2 (I_{\text{O(MAX)}})(C_{\text{RSS}})(f)
\]

\[
P_{\text{BOT}} = \left( \frac{V_{\text{IN}} - V_{\text{OUT}}}{V_{\text{IN}}} \right) (I_{\text{O(MAX)}})^2 \left( \rho_{\text{TOP}} \right) (R_{\text{DS(ON)}})
\]

Both MOSFETs have \(I^2R\) losses and the \(P_{\text{TOP}}\) equation includes an additional term for transition losses, which are largest at high input voltages. The constant \(k = 1.7\) can be used to estimate the amount of transition loss. The bottom MOSFET losses are greatest at high input voltage or during a short circuit when the duty cycle is nearly 100%.

**Operating Frequency and Synchronization**

The choice of operating frequency and inductor value is a trade-off between efficiency and component size. Low frequency operation improves efficiency by reducing MOSFET switching losses, both gate charge loss and transition loss. However, lower frequency operation requires more inductance for a given amount of ripple current.

The internal oscillator runs at a nominal 150kHz frequency when the SYNC pin is left open or connected to ground. Pulling the SYNC pin above 1.2V will increase the frequency by 50%. The oscillator will injection lock to a clock signal applied to the SYNC pin with a frequency between 165kHz and 200kHz. The clock high level must exceed 1.2V for at least 1\(\mu\)s and no longer than 4\(\mu\)s as shown in Figure 4. The top MOSFET turn-on will synchronize with the rising edge of the clock.

**Inductor Value Selection**

Given the desired input and output voltages, the inductor value and operating frequency directly determine the ripple current:

\[
\Delta I_L = \left( \frac{V_{\text{OUT}}}{(f)(L)} \right) \left( 1 - \frac{V_{\text{OUT}}}{V_{\text{IN}}} \right)
\]

Lower ripple current reduces core losses in the inductor, ESR losses in the output capacitors and output voltage ripple. Thus, highest efficiency operation is obtained at low frequency with small ripple current. To achieve this, however, requires a large inductor.

A reasonable starting point is to choose a ripple current that is about 40% of \(I_{\text{O(MAX)}}\). Note that the largest ripple current occurs at the highest \(V_{\text{IN}}\). To guarantee that ripple current does not exceed a specified maximum, the inductor should be chosen according to:

\[
L \geq \left( \frac{V_{\text{OUT}}}{(f)(\Delta I_{\text{L(MAX)}})} \right) \left( 1 - \frac{V_{\text{OUT}}}{V_{\text{IN(MAX)}}} \right)
\]

**Burst Mode Operation Considerations**

The choice of \(R_{\text{DS(ON)}}\) and inductor value also determines the load current at which the LTC1625 enters Burst Mode operation. When bursting, the controller clamps the peak inductor current to approximately:

\[
I_{\text{BURST(PEAK)}} = \frac{30\text{mV}}{R_{\text{DS(ON)}}}
\]
The corresponding average current depends on the amount of ripple current. Lower inductor values (higher $\Delta I_L$) will reduce the load current at which Burst Mode operation begins.

The output voltage ripple can increase during Burst Mode operation if $\Delta I_L$ is substantially less than $I_{BURST}$. This will primarily occur when the duty cycle is very close to unity ($V_{IN}$ is close to $V_{OUT}$) or if very large value inductors are chosen. This is generally only a concern in applications with $V_{OUT} \geq 5V$. At high duty cycles, a skipped cycle causes the inductor current to quickly descend to zero. However, it takes multiple cycles to ramp the current back up to $I_{BURST(PEAK)}$. During this interval, the output capacitor must supply the load current and enough charge may be lost to cause significant droop in the output voltage. It is a good idea to keep $\Delta I_L$ comparable to $I_{BURST(PEAK)}$. Otherwise, one might need to increase the output capacitance in order to reduce the voltage ripple or else disable Burst Mode operation by forcing continuous operation with the FCB pin.

Fault Conditions: Current Limit and Output Shorts

The LTC1625 current comparator can accommodate a maximum sense voltage of 150mV. This voltage and the sense resistance determine the maximum allowed peak inductor current. The corresponding output current limit is:

$$I_{LIMIT} = \frac{150mV}{(R_{DS(ON)})\rho_T} - \frac{1}{2} \Delta I_L$$

The current limit value should be checked to ensure that $I_{LIMIT(MIN)} > I_{O(MAX)}$. The minimum value of current limit generally occurs with the largest $V_{IN}$ at the highest ambient temperature, conditions which cause the highest power dissipation in the top MOSFET. Note that it is important to check for self-consistency between the assumed junction temperature of the top MOSFET and the resulting value of $I_{LIMIT}$ which heats the junction.

Caution should be used when setting the current limit based upon $R_{DS(ON)}$ of the MOSFETs. The maximum current limit is determined by the minimum MOSFET on-resistance. Data sheets typically specify nominal and maximum values for $R_{DS(ON)}$, but not a minimum. A reasonable, but perhaps overly conservative, assumption is that the minimum $R_{DS(ON)}$ lies the same amount below the typical value as the maximum $R_{DS(ON)}$ lies above it. Consult the MOSFET manufacturer for further guidelines.

The LTC1625 includes current foldback to help further limit load current when the output is shorted to ground. If the output falls by more than half, then the maximum sense voltage is progressively lowered from 150mV to 30mV. Under short-circuit conditions with very low duty cycle, the LTC1625 will begin skipping cycles in order to limit the short-circuit current. In this situation the bottom MOSFET $R_{DS(ON)}$ will control the inductor current trough rather than the top MOSFET controlling the inductor current peak. The short-circuit ripple current is determined by the minimum on-time $t_{ON(MIN)}$ of the LTC1625 (approximately 0.5 $\mu$s), the input voltage, and inductor value:

$$\Delta I_L(SC) = t_{ON(MIN)} \frac{V_{IN}}{L}.$$
Ferrite designs have very low core loss and are preferred at high switching frequencies, so design goals can concentrate on copper loss and preventing saturation. Ferrite core material saturates "hard," which means that inductance collapses rapidly when the peak design current is exceeded. This results in an abrupt increase in inductor ripple current and consequent output voltage ripple. Do not allow the core to saturate!

Molypermalloy (from Magnetics, Inc.) is a very good, low loss core material for toroids, but it is more expensive than ferrite. A reasonable compromise from the same manufacturer is Kool Mµ. Toroids are very space efficient, especially when you can use several layers of wire. Because they generally lack a bobbin, mounting is more difficult. However, designs for surface mount are available which do not increase the height significantly.

**Schottky Diode Selection**

The Schottky diode D1 shown in Figure 1 conducts during the dead time between the conduction of the power MOSFETs. This prevents the body diode of the bottom MOSFET from turning on and storing charge during the dead time, which could cost as much as 1% in efficiency. A 1A Schottky diode is generally a good size for 3A to 5A regulators. The diode may be omitted if the efficiency loss can be tolerated.

**C\text{IN} and C\text{OUT Selection}**

In continuous mode, the drain current of the top MOSFET is approximately a square wave of duty cycle \( V_{\text{OUT}} / V_{\text{IN}} \). To prevent large input voltage transients, a low ESR input capacitor sized for the maximum RMS current must be used. The maximum RMS current is given by:

\[
I_{\text{RMS}} = I_{\text{O(MAX)}} \left( \frac{V_{\text{IN}}}{V_{\text{OUT}}} - 1 \right)^{1/2}
\]

This formula has a maximum at \( V_{\text{IN}} = 2V_{\text{OUT}} \), where \( I_{\text{RMS}} = I_{\text{O(MAX)}}/2 \). This simple worst-case condition is commonly used for design because even significant deviations do not offer much relief. Note that ripple current ratings from capacitor manufacturers are often based on only 2000 hours of life. This makes it advisable to further derate the capacitor or to choose a capacitor rated at a higher temperature than required. Several capacitors may also be placed in parallel to meet size or height requirements in the design.

The selection of \( C_{\text{OUT}} \) is primarily determined by the ESR required to minimize voltage ripple. The output ripple \( \Delta V_{\text{OUT}} \) is approximately bounded by:

\[
\Delta V_{\text{OUT}} \leq \Delta I_{L} \left( \frac{1}{ESR + \frac{1}{(8)(f)(C_{\text{OUT}})}} \right)
\]

Since \( \Delta I_{L} \) increases with input voltage, the output ripple is highest at maximum input voltage. Typically, once the ESR requirement is satisfied the capacitance is adequate for filtering and has the required RMS current rating.

Manufacturers such as Nichicon, United Chemicon and Sanyo should be considered for high performance through-hole capacitors. The OS-CON semiconductor dielectric capacitor available from Sanyo has the lowest product of ESR and size of any aluminum electrolytic at a somewhat higher price.

In surface mount applications, multiple capacitors may have to be placed in parallel to meet the ESR requirement. Aluminum electrolytic and dry tantalum capacitors are both available in surface mount packages. In the case of tantalum, it is critical that the capacitors have been surge tested for use in switching power supplies. An excellent choice is the AVX TPS series of surface mount tantalum, available in case heights ranging from 2mm to 4mm. Other capacitor types include Sanyo OS-CON, Nichicon PL series, and Sprague 593D and 595D series. Consult the manufacturer for other specific recommendations.

**INTV\text{CC} Regulator**

An internal P-channel low dropout regulator produces the 5.2V supply which powers the drivers and internal circuitry within the LTC1625. The INTV\text{CC} pin can supply up to 50mA and must be bypassed to ground with a minimum of 4.7µF tantalum or low ESR electrolytic capacitance. Good bypassing is necessary to supply the high transient currents required by the MOSFET gate drivers.
Applications Information

High input voltage applications in which large MOSFETs are being driven at high frequencies may cause the LTC1625 to exceed its maximum junction temperature rating. Most of the supply current drives the MOSFET gates unless an external EXTVCC source is used. The junction temperature can be estimated from the equations given in Note 2 of the Electrical Characteristics. For example, the LTC1625CGN is limited to less than 14mA from a 30V supply:

\[
T_J = 70°C + (14mA)(30V)(130°C/W) = 125°C
\]

To prevent the maximum junction temperature from being exceeded, the input supply current must be checked when operating in continuous mode at high \(V_{IN}\).

EXTVCC Connection

The LTC1625 contains an internal P-channel MOSFET switch connected between the EXTVCC and INTVCC pins. Whenever the EXTVCC pin is above 4.7V the internal 5.2V regulator shuts off, the switch closes and INTVCC power is supplied via EXTVCC until EXTVCC drops below 4.5V. This allows the MOSFET gate drive and control power to be derived from the output or other external source during normal operation. When the output is out of regulation (start-up, short circuit) power is supplied from the internal regulator. Do not apply greater than 7V to the EXTVCC pin and ensure that \(EXTVCC \leq V_{IN}\).

Significant efficiency gains can be realized by powering INTVCC from the output, since the \(V_{IN}\) current supplying the driver and control currents will be scaled by a factor of Duty Cycle/Efficiency. For 5V regulators this simply means connecting the EXTVCC pin directly to \(V_{OUT}\). However, for 3.3V and other lower voltage regulators, additional circuitry is required to derive INTVCC power from the output.

The following list summarizes the four possible connections for EXTVCC:

1. EXTVCC left open (or grounded). This will cause INTVCC to be powered from the internal 5.2V regulator resulting in an efficiency penalty of up to 10% at high input voltages.

2. EXTVCC connected directly to \(V_{OUT}\). This is the normal connection for a 5V regulator and provides the highest efficiency.

3. EXTVCC connected to an output-derived boost network. For 3.3V and other low voltage regulators, efficiency gains can still be realized by connecting EXTVCC to an output-derived voltage which has been boosted to greater than 4.7V. This can be done with either an inductive boost winding as shown in Figure 5a or a capacitive charge pump as shown in Figure 5b.

4. EXTVCC connected to an external supply. If an external supply is available in the 5V to 7V range (\(EXTVCC < V_{IN}\)), it may be used to power EXTVCC providing it is compatible with the MOSFET gate drive requirements.
APPLICATIONS INFORMATION

Note that $R_{DS(ON)}$ also varies with the gate drive level. If gate drives other than the 5.2V $INTVCC$ are used, this must be accounted for when selecting the MOSFET $R_{DS(ON)}$. Particular care should be taken with applications where $EXTVCC$ is connected to the output. When the output voltage is between 4.7V and 5.2V, $INTVCC$ will be connected to the output and the gate drive is reduced. The resulting increase in $R_{DS(ON)}$ will also lower the current limit. Even applications with $V_{OUT} > 5.2V$ will traverse this region during start-up and must take into account the reduced current limit.

**Topside MOSFET Driver Supply ($C_B$, $D_B$)**

An external bootstrap capacitor ($C_B$ in the functional diagram) connected to the BOOST pin supplies the gate drive voltage for the topside MOSFET. This capacitor is charged through diode $D_B$ from $INTVCC$ when the SW node is low. Note that the voltage across $C_B$ is about a diode drop below $INTVCC$. When the top MOSFET turns on, the switch node voltage rises to $V_{IN}$ and the BOOST pin rises to approximately $V_{IN} + INTVCC$. During dropout operation, $C_B$ supplies the top driver for as long as ten cycles between refreshes. Thus, the boost capacitance needs to store about 100 times the gate charge required by the top MOSFET. In many applications 0.22µF is adequate.

*When adjusting the gate drive level, the final arbiter is the total input current for the regulator. If you make a change and the input current decreases, then you improved the efficiency. If there is no change in input current, then there is no change in efficiency.*

**Output Voltage Programming**

The LTC1625 has a pin selectable output voltage determined by the $V_{PROG}$ pin as follows:

- $V_{PROG} = 0V$, $V_{OUT} = 3.3V$
- $V_{PROG} = INTVCC$, $V_{OUT} = 5V$
- $V_{PROG} = Open$, $V_{OUT} = Adjustable$

Remote sensing of the output voltage is provided by the $V_{OSENSE}$ pin. For fixed 3.3V and 5V output applications an internal resistive divider is used and the $V_{OSENSE}$ pin is connected directly to the output voltage as shown in Figure 6a. When using an external resistive divider, the $V_{PROG}$ pin is left open and the $V_{OSENSE}$ pin is connected to feedback resistors as shown in Figure 6b. The output voltage is set by the divider as:

$$V_{OUT} = 1.19V \left(1 + \frac{R_2}{R_1}\right)$$

**Run/Soft Start Function**

The RUN/SS pin is a dual purpose pin that provides a soft start function and a means to shut down the LTC1625. Soft start reduces surge currents from $V_{IN}$ by gradually increasing the controller’s current limit $I_{TH(MAX)}$. This pin can also be used for power supply sequencing.

Pulling the RUN/SS pin below 1.4V puts the LTC1625 into a low quiescent current shutdown ($I_Q < 30\mu A$). This pin can be driven directly from logic as shown in Figure 7. Releasing the RUN/SS pin allows an internal 3µA current source to charge up the external capacitor $C_{SS}$. If RUN/SS has been pulled all the way to ground there is a delay before starting of approximately:
APPLICATIONS INFORMATION

When the voltage on RUN/SS reaches 1.4V the LTC1625 begins operating with a clamp on I_TH at 0.8V. As the voltage on RUN/SS increases to approximately 3.1V, the clamp on I_TH is raised until its full 2.4V range is restored. This takes an additional 0.5s/µF. During this time the load current will be folded back to approximately 30mV/R_DS(ON) until the output reaches half of its final value.

Diode D1 in Figure 7 reduces the start delay while allowing C SS to charge up slowly for the soft start function. This diode and C SS can be deleted if soft start is not needed. The RUN/SS pin has an internal 6V zener clamp (See Functional Diagram).

The secondary output voltage V_SEC is normally set as shown in Figure 5a by the turns ratio N of the transformer:

\[ V_{SEC} = (N + 1)V_{OUT} \]

However, if the controller goes into Burst Mode operation and halts switching due to a light primary load current, then V_SEC will droop. An external resistor divider from V_SEC to the FCB pin sets a minimum voltage V_SEC(MIN):

\[ V_{SEC(MIN)} = 1.19V \left( 1 + \frac{R_4}{R_3} \right) \]

If V_SEC drops below this level, the FCB voltage forces continuous operation until V_SEC is again above its minimum.

Minimum On-Time Considerations

Minimum on-time t_ON(MIN) is the smallest amount of time that the LTC1625 is capable of turning the top MOSFET on and off again. It is determined by internal timing delays and the amount of gate charge required to turn on the top MOSFET. Low duty cycle applications may approach this minimum on-time limit and care should be taken to ensure that:

\[ t_{V_{OUT}} < \frac{V_{OUT}}{(V_{IN})(f)} \]

If the duty cycle falls below what can be accommodated by the minimum on-time, the LTC1625 will begin to skip cycles. The output voltage will continue to be regulated, but the ripple current and ripple voltage will increase.

The minimum on-time for the LTC1625 is generally about 0.5µs. However, as the peak sense voltage \( I_{L(PEAK)} \cdot R_DS(ON) \) decreases, the minimum on-time gradually increases up to about 0.7µs. This is of particular concern in forced continuous applications with low ripple current at light loads. If the duty cycle drops below the minimum on-time limit in this situation, a significant amount of cycle skipping can occur with correspondingly larger current and voltage ripple.

Efficiency Considerations

The efficiency of a switching regulator is equal to the output power divided by the input power \((\times100\%).\) Percent efficiency can be expressed as:

\[ \%\text{Efficiency} = 100\% - (L_1 + L_2 + L_3 + ...) \]
where L1, L2, etc. are the individual losses as a percentage of input power. It is often useful to analyze individual losses to determine what is limiting the efficiency and which change would produce the most improvement. Although all dissipative elements in the circuit produce losses, four main sources usually account for most of the losses in LTC1625 circuits:

1. INTVCC current. This is the sum of the MOSFET driver and control currents. The driver current results from switching the gate capacitance of the power MOSFETs. Each time a MOSFET gate is switched on and then off, a packet of gate charge Qg moves from INTVCC to ground. The resulting current out of INTVCC is typically much larger than the control circuit current. In continuous mode, IGATECHG = f(Qg(TOP) + Qg(BOT)).

By powering EXTVCC from an output-derived source, the additional VIN current resulting from the driver and control currents will be scaled by a factor of Duty Cycle/Efficiency. For example, in a 20V to 5V application at 400mA load, 10mA of INTVCC current results in approximately 3mA of VIN current. This reduces the loss from 10% (if the driver was powered directly from VIN) to about 3%.

2. DC I^2R Losses. Since there is no separate sense resistor, DC I^2R losses arise only from the resistances of the MOSFETs and inductor. In continuous mode the average output current flows through L, but is "chopped" between the top MOSFET and the bottom MOSFET. If the two MOSFETs have approximately the same RDS(ON), then the resistance of one MOSFET can simply be summed with the resistance of L to obtain the DC I^2R loss. For example, if each RDS(ON) = 0.05Ω and RL = 0.15Ω, then the total resistance is 0.2Ω. This results in losses ranging from 2% to 8% as the output current increases from 0.5A to 2A for a 5V output. I^2R losses cause the efficiency to drop at high output currents.

3. Transition losses apply only to the topside MOSFET, and only when operating at high input voltages (typically 20V or greater). Transition losses can be estimated from:

\[
\text{Transition Loss} = (1.7)(V_{IN}^2)(I_{O(MAX)})(C_{RSS})(f)
\]

4. LTC1625 VIN supply current. The VIN current is the DC supply current to the controller excluding MOSFET gate drive current. Total supply current is typically about 850µA. If EXTVCC is connected to 5V, the LTC1625 will draw only 330µA from VIN and the remaining 520µA will come from EXTVCC. VIN current results in a small (<1%) loss which increases with VIN.

Other losses including CIN and COUT ESR dissipative losses, Schottky conduction losses during dead time and inductor core losses, generally account for less than 2% total additional loss.

Checking Transient Response

The regulator loop response can be checked by looking at the load transient response. Switching regulators take several cycles to respond to a step in DC (resistive) load current. When a load step occurs, VOUT immediately shifts by an amount equal to (∆ILOAD)(ESR), where ESR is the effective series resistance of COUT, and COUT begins to charge or discharge. The regulator loop acts on the resulting feedback error signal to return VOUT to its steady-state value. During this recovery time VOUT can be monitored for overshoot or ringing which would indicate a stability problem. The ITH pin external components shown in Figure 1 will provide adequate compensation for most applications.

A second, more severe transient is caused by connecting loads with large (> 1µF) supply bypass capacitors. The discharged bypass capacitors are effectively put in parallel with COUT, causing a rapid drop in VOUT. No regulator can deliver enough current to prevent this problem if the load switch resistance is low and it is driven quickly. The only solution is to limit the rise time of the switch drive in order to limit the inrush current to the load.

Automotive Considerations: Plugging into the Cigarette Lighter

As battery-powered devices go mobile, there is a natural interest in plugging into the cigarette lighter in order to conserve or even recharge battery packs during operation. But before you connect, be advised: you are plugging into the supply from hell. The main battery line in an
**APPLICATIONS INFORMATION**

**WU UU**

automobile is the source of a number of nasty potential transients, including load dump, reverse and double battery.

Load dump is the result of a loose battery cable. When the cable breaks connection, the field collapse in the alternator can cause a positive spike as high as 60V which takes several hundred milliseconds to decay. Reverse battery is just what it says, while double battery is a consequence of tow truck operators finding that a 24V jump start cranks cold engines faster than 12V.

The network shown in Figure 8 is the most straightforward approach to protect a DC/DC converter from the ravages of an automotive battery line. The series diode prevents current from flowing during reverse battery, while the transient suppressor clamps the input voltage during load dump. Note that the transient suppressor should not conduct during double-battery operation, but must still clamp the input voltage below breakdown of the converter. Although the LTC1625 has a maximum input voltage of 36V, most applications will be limited to 30V by the MOSFET $V_{BRDSS}$.

For 40% ripple current at maximum $V_{IN}$ the inductor should be:

$$L \geq \frac{3.3V}{(225kHz)(0.4)(2A)} \left(1 - \frac{3.3V}{22V}\right) = 16\mu H$$

Choosing a standard value of 15µH results in a maximum ripple current of:

$$\Delta I_{(MAX)} = \frac{3.3V}{(225kHz)(15\mu H)} \left(1 - \frac{3.3V}{22V}\right) = 0.83A$$

Next, check that the minimum value of the current limit is acceptable. Assume a junction temperature close to a 70°C ambient with $\rho_{80^\circ C} = 1.3$.

$$I_{LIMIT} \geq \frac{150mV}{(0.042\Omega)(1.3)} - \frac{1}{2} 0.83A = 2.3A$$

This is comfortably above $I_{O(MAX)} = 2A$. Now double-check the assumed $T_J$:

$$P_{TOP} = \frac{3.3V}{22V} (2.3A)^2 (1.3)(0.042\Omega) + \frac{(1.7)(22)^2 (2.3A)(180pF)(225kHz)}{225kHz} = 43mW + 77mW = 120mW$$

$$T_J = 70^\circ C + (120mW)(50^\circ C/W) = 76^\circ C$$

Since $\rho(76^\circ C) \approx \rho(80^\circ C)$, the solution is self-consistent.

A short circuit to ground will result in a folded back current of:

$$I_{SC} = \frac{30mV}{(0.03\Omega)(1.1)} + \frac{1}{2} \left(\frac{15V}{15\mu H}\right) = 1.2A$$

with a typical value of $R_{DS(ON)}$ and $\rho(50^\circ C) = 1.1$. The resulting power dissipated in the bottom MOSFET is:

$$P_{BOT} = \frac{15V - 3.3V}{15V} (1.2A)^2 (1.1)(0.03\Omega) = 37mW$$

which is less than under full load conditions.

---

**Figure 8. Automotive Application Protection**

**Design Example**

As a design example, take a supply with the following specifications: $V_{IN} = 12V$ to 22V (15V nominal), $V_{OUT} = 3.3V$, $I_{O(MAX)} = 2A$, and $f = 225kHz$. The required $R_{DS(ON)}$ can immediately be estimated:

$$R_{DS(ON)} = \frac{120mV}{(2A)(1.3)} = 0.046\Omega$$

A 0.042Ω Siliconix Si4412DY MOSFET ($\theta_{JA} = 50^\circ C/W$) is close to this value.
C\text{IN} is chosen for an RMS current rating of at least 1A at temperature. C\text{OUT} is chosen with an ESR of 0.033\,\Omega for low output ripple. The output ripple in continuous mode will be highest at the maximum input voltage and is approximately:

\[ \Delta V_O = (\Delta I_{L\text{MAX}})(\text{ESR}) = (0.83\,\text{A})(0.033\,\Omega) = 27\,\text{mV} \]

The complete circuit is shown in Figure 9.

**PC Board Layout Checklist**

When laying out the printed circuit board, the following checklist should be used to ensure proper operation of the LTC1625. These items are also illustrated graphically in the layout diagram of Figure 10. Check the following in your layout:

1) Connect the TK lead directly to the drain of the topside MOSFET. Then connect the drain to the (+) plate of C\text{IN}. This capacitor provides the AC current to the top MOSFET.

2) The power ground pin connects directly to the source of the bottom N-channel MOSFET. Then connect the source to the anode of the Schottky diode and (−) plate of C\text{IN}, which should have as short lead lengths as possible.

3) The LTC1625 signal ground pin must return to the (−) plate of C\text{OUT}. Connect the (−) plate of C\text{OUT} to power ground at the source of the bottom MOSFET.

4) Keep the switch node SW away from sensitive small-signal nodes. Ideally the switch node should be placed on the opposite side of the power MOSFETs from the LTC1625.

5) Connect the INTV\text{CC} decoupling capacitor C\text{VCC} closely to the INTV\text{CC} pin and the power ground pin. This capacitor carries the MOSFET gate drive current.

6) Does the VOSENS\text{E} pin connect directly to the (+) plate of C\text{OUT}? In adjustable applications, the resistive divider (R1, R2) must be connected between the (+) plate of C\text{OUT} and signal ground. Place the divider near the LTC1625 in order to keep the high impedance VOSENS\text{E} node short.

7) For applications with multiple switching power converters connected to the same V\text{IN}, ensure that the input filter capacitance for the LTC1625 is not shared with the other converters. AC input current from another converter will cause substantial input voltage ripple that may interfere with proper operation of the LTC1625. A few inches of PC trace or wire (≈100\,\text{nm}) between C\text{IN} and V\text{IN} is sufficient to prevent sharing.
