SECTION 6
TEMPERATURE SENSORS

Walt Kester

INTRODUCTION

Measurement of temperature is critical in modern electronic devices, especially expensive laptop computers and other portable devices with densely packed circuits which dissipate considerable power in the form of heat. Knowledge of system temperature can also be used to control battery charging as well as prevent damage to expensive microprocessors.

Compact high power portable equipment often has fan cooling to maintain junction temperatures at proper levels. In order to conserve battery life, the fan should only operate when necessary. Accurate control of the fan requires a knowledge of critical temperatures from the appropriate temperature sensor.

APPLICATIONS OF TEMPERATURE SENSORS

- Monitoring
  - Portable Equipment
  - CPU Temperature
  - Battery Temperature
  - Ambient Temperature

- Compensation
  - Oscillator Drift in Cellular Phones
  - Thermocouple Cold-Junction Compensation

- Control
  - Battery Charging
  - Process Control

Figure 6.1

Accurate temperature measurements are required in many other measurement systems such as process control and instrumentation applications. In most cases, because of low-level nonlinear outputs, the sensor output must be properly conditioned and amplified before further processing can occur.

Except for IC sensors, all temperature sensors have nonlinear transfer functions. In the past, complex analog conditioning circuits were designed to correct for the sensor nonlinearity. These circuits often required manual calibration and precision resistors to achieve the desired accuracy. Today, however, sensor outputs may be
Temperature Sensors

digitized directly by high resolution ADCs. Linearization and calibration is then performed digitally, thereby reducing cost and complexity.

Resistance Temperature Devices (RTDs) are accurate, but require excitation current and are generally used in bridge circuits. Thermistors have the most sensitivity but are the most non-linear. However, they are popular in portable applications such as measurement of battery temperature and other critical temperatures in a system.

Modern semiconductor temperature sensors offer high accuracy and high linearity over an operating range of about −55°C to +150°C. Internal amplifiers can scale the output to convenient values, such as 10mV/°C. They are also useful in cold-junction-compensation circuits for wide temperature range thermocouples. Semiconductor temperature sensors can be integrated into multi-function ICs which perform a number of other hardware monitoring functions.

Figure 6.2 lists the most popular types of temperature transducers and their characteristics.

Thermocouple Principles and Cold-Junction Compensation

Thermocouples are small, rugged, relatively inexpensive, and operate over the widest range of all temperature sensors. They are especially useful for making measurements at extremely high temperatures (up to +2300°C) in hostile environments. They produce only millivolts of output, however, and require precision amplification for further processing. They also require cold-junction-compensation (CJC) techniques which will be discussed shortly. They are more linear than many other sensors, and their non-linearity has been well characterized. Some common thermocouples are shown in Figure 6.3. The most common metals used are Iron, Platinum, Rhodium, Rhenium, Tungsten, Copper, Alumel (composed
of Nickel and Aluminum), Chromel (composed of Nickel and Chromium) and Constantan (composed of Copper and Nickel).

Figure 6.3

Figure 6.4 shows the voltage-temperature curves of three commonly used thermocouples, referred to a 0°C fixed-temperature reference junction. Of the thermocouples shown, Type J thermocouples are the most sensitive, producing the largest output voltage for a given temperature change. On the other hand, Type S thermocouples are the least sensitive. These characteristics are very important to consider when designing signal conditioning circuitry in that the thermocouples’ relatively low output signals require low-noise, low-drift, high-gain amplifiers.

To understand thermocouple behavior, it is necessary to consider the non-linearities in their response to temperature differences. Figure 6.4 shows the relationships between sensing junction temperature and voltage output for a number of thermocouple types (in all cases, the reference cold junction is maintained at 0°C). It is evident that the responses are not quite linear, but the nature of the non-linearity is not so obvious.

Figure 6.5 shows how the Seebeck coefficient (the change of output voltage with change of sensor junction temperature - i.e., the first derivative of output with respect to temperature) varies with sensor junction temperature (we are still considering the case where the reference junction is maintained at 0°C).

When selecting a thermocouple for making measurements over a particular range of temperature, we should choose a thermocouple whose Seebeck coefficient varies as little as possible over that range.
THERMOCOUPLE OUTPUT VOLTAGES FOR TYPE J, K, AND S THERMOCOUPLES

Figure 6.4

THERMOCOUPLE SEEBECK COEFFICIENT VERSUS TEMPERATURE

Figure 6.5
For example, a Type J thermocouple has a Seebeck coefficient which varies by less than 1µV/°C between 200 and 500°C, which makes it ideal for measurements in this range.

Presenting these data on thermocouples serves two purposes: First, Figure 6.4 illustrates the range and sensitivity of the three thermocouple types so that the system designer can, at a glance, determine that a Type S thermocouple has the widest useful temperature range, but a Type J thermocouple is more sensitive. Second, the Seebeck coefficients provide a quick guide to a thermocouple's linearity. Using Figure 6.5, the system designer can choose a Type K thermocouple for its linear Seebeck coefficient over the range of 400°C to 800°C or a Type S over the range of 900°C to 1700°C. The behavior of a thermocouple’s Seebeck coefficient is important in applications where variations of temperature rather than absolute magnitude are important. These data also indicate what performance is required of the associated signal conditioning circuitry.

To use thermocouples successfully we must understand their basic principles. Consider the diagrams in Figure 6.6.

![THERMOCOUPLE BASICS](image)

If we join two dissimilar metals at any temperature above absolute zero, there will be a potential difference between them (their “thermoelectric e.m.f.” or “contact potential”) which is a function of the temperature of the junction (Figure 6.6A). If we join the two wires at two places, two junctions are formed (Figure 6.6B). If the two junctions are at different temperatures, there will be a net e.m.f. in the circuit, and a current will flow determined by the e.m.f. and the total resistance in the circuit (Figure 6.6B). If we break one of the wires, the voltage across the break will be
equal to the net thermoelectric e.m.f. of the circuit, and if we measure this voltage, we can use it to calculate the temperature difference between the two junctions (Figure 6.6C). We must always remember that a thermocouple measures the temperature difference between two junctions, not the absolute temperature at one junction. We can only measure the temperature at the measuring junction if we know the temperature of the other junction (often called the "reference" junction or the "cold" junction).

But it is not so easy to measure the voltage generated by a thermocouple. Suppose that we attach a voltmeter to the circuit in Figure 6.6C (Figure 6.6D). The wires attached to the voltmeter will form further thermojunctions where they are attached. If both these additional junctions are at the same temperature (it does not matter what temperature), then the "Law of Intermediate Metals" states that they will make no net contribution to the total e.m.f. of the system. If they are at different temperatures, they will introduce errors. Since every pair of dissimilar metals in contact generates a thermoelectric e.m.f. (including copper/solder, kovar/copper [kovar is the alloy used for IC leadframes] and aluminum/kovar [at the bond inside the IC]), it is obvious that in practical circuits the problem is even more complex, and it is necessary to take extreme care to ensure that all the junction pairs in the circuitry around a thermocouple, except the measurement and reference junctions themselves, are at the same temperature.

Thermocouples generate a voltage, albeit a very small one, and do not require excitation. As shown in Figure 6.6D, however, two junctions (T1, the measurement junction and T2, the reference junction) are involved. If T2 = T1, then V2 = V1, and the output voltage V = 0. Thermocouple output voltages are often defined with a reference junction temperature of 0°C (hence the term cold or ice point junction), so the thermocouple provides an output voltage of 0V at 0°C. To maintain system accuracy, the reference junction must therefore be at a well-defined temperature (but not necessarily 0°C). A conceptually simple approach to this need is shown in Figure 6.7. Although an ice/water bath is relatively easy to define, it is quite inconvenient to maintain.

Today an ice-point reference, and its inconvenient ice/water bath, is generally replaced by electronics. A temperature sensor of another sort (often a semiconductor sensor, sometimes a thermistor) measures the temperature of the cold junction and is used to inject a voltage into the thermocouple circuit which compensates for the difference between the actual cold junction temperature and its ideal value (usually 0°C) as shown in Figure 6.8. Ideally, the compensation voltage should be an exact match for the difference voltage required, which is why the diagram gives the voltage as f(T2) (a function of T2) rather than KT2, where K is a simple constant. In practice, since the cold junction is rarely more than a few tens of degrees from 0°C, and generally varies by little more than ±10°C, a linear approximation (V=KT2) to the more complex reality is sufficiently accurate and is what is often used. (The expression for the output voltage of a thermocouple with its measuring junction at T°C and its reference at 0°C is a polynomial of the form V = K1T + K2T² + K3T³ + ..., but the values of the coefficients K2, K3, etc. are very small for most common types of thermocouple. References 8 and 9 give the values of these coefficients for a wide range of thermocouples.)
CLASSICAL COLD-JUNCTION COMPENSATION USING AN ICE-POINT (0°C) REFERENCE JUNCTION

![Diagram of classical cold-junction compensation](image)

\]

IF \( V(\text{COMP}) = V(T2) - V(0^\circ C) \), THEN

\[
V(\text{OUT}) = V(T1) - V(0^\circ C)
\]

**Figure 6.8**
When electronic cold-junction compensation is used, it is common practice to eliminate the additional thermocouple wire and terminate the thermocouple leads in the isothermal block in the arrangement shown in Figure 6.9. The Metal A-Copper and the Metal B-Copper junctions, if at the same temperature, are equivalent to the Metal A-Metal B thermocouple junction in Figure 6.8.

The circuit in Figure 6.10 conditions the output of a Type K thermocouple, while providing cold-junction compensation, for temperatures between 0ºC and 250ºC. The circuit operates from single +3.3V to +12V supplies and has been designed to produce an output voltage transfer characteristic of 10mV/ºC.

A Type K thermocouple exhibits a Seebeck coefficient of approximately 41µV/ºC; therefore, at the cold junction, the TMP35 voltage output sensor with a temperature coefficient of 10mV/ºC is used with R1 and R2 to introduce an opposing cold-junction temperature coefficient of −41µV/ºC. This prevents the isothermal, cold-junction connection between the circuit’s printed circuit board traces and the thermocouple’s wires from introducing an error in the measured temperature. This compensation works extremely well for circuit ambient temperatures in the range of 20ºC to 50ºC. Over a 250ºC measurement temperature range, the thermocouple produces an output voltage change of 10.151mV. Since the required circuit’s output full-scale voltage change is 2.5V, the gain of the circuit is set to 246.3. Choosing R4 equal to 4.99kΩ sets R5 equal to 1.22MΩ. Since the closest 1% value for R5 is 1.21MΩ, a 50kΩ potentiometer is used with R5 for fine trim of the full-scale output voltage. Although the OP193 is a single-supply op amp, its output stage is not rail-to-rail, and will only go down to about 0.1V above ground. For this reason, R3 is added to the circuit to supply an output offset voltage of about 0.1V for a nominal supply voltage of 5V. This offset (10°C) must be subtracted when making measurements.
referenced to the OP193 output. R3 also provides an open thermocouple detection, forcing the output voltage to greater than 3V should the thermocouple open. Resistor R7 balances the DC input impedance of the OP193, and the 0.1µF film capacitor reduces noise coupling into its non-inverting input.

![Diagram](image)

**Figure 6.10**

The AD594/AD595 is a complete instrumentation amplifier and thermocouple cold junction compensator on a monolithic chip (see Figure 6.11). It combines an ice point reference with a precalibrated amplifier to provide a high level (10mV/°C) output directly from the thermocouple signal. Pin-strapping options allow it to be used as a linear amplifier-compensator or as a switched output set-point controller using either fixed or remote set-point control. It can be used to amplify its compensation voltage directly, thereby becoming a stand-alone Celsius transducer with 10mV/°C output. In such applications it is very important that the IC chip is at the same temperature as the cold junction of the thermocouple, which is usually achieved by keeping the two in close proximity and isolated from any heat sources.

The AD594/AD595 includes a thermocouple failure alarm that indicates if one or both thermocouple leads open. The alarm output has a flexible format which includes TTL drive capability. The device can be powered from a single-ended supply (which may be as low as +5V), but by including a negative supply, temperatures below 0°C can be measured. To minimize self-heating, an unloaded AD594/AD595 will operate with a supply current of 160µA, but is also capable of delivering ±5mA to a load.

The AD594 is precalibrated by laser wafer trimming to match the characteristics of type J (iron/constantan) thermocouples, and the AD595 is laser trimmed for type K...
TEMPERATURE SENSORS

(chromel/alumel). The temperature transducer voltages and gain control resistors are available at the package pins so that the circuit can be recalibrated for other thermocouple types by the addition of resistors. These terminals also allow more precise calibration for both thermocouple and thermometer applications. The AD594/AD595 is available in two performance grades. The C and the A versions have calibration accuracies of ±1°C and ±3°C, respectively. Both are designed to be used with cold junctions between 0 to +50°C. The circuit shown in Figure 6.11 will provide a direct output from a type J thermocouple (AD594) or a type K thermocouple (AD595) capable of measuring 0 to +300°C.

AD594/AD595 MONOLITHIC THERMOCOUPLE AMPLIFIERS WITH COLD-JUNCTION COMPENSATION

![Circuit Diagram]

Figure 6.11

The AD596/AD597 are monolithic set-point controllers which have been optimized for use at elevated temperatures as are found in oven control applications. The device cold-junction compensates and amplifies a type J/K thermocouple to derive an internal signal proportional to temperature. They can be configured to provide a voltage output (10mV/°C) directly from type J/K thermocouple signals. The device is packaged in a 10-pin metal can and is trimmed to operate over an ambient range from +25°C to +100°C. The AD596 will amplify thermocouple signals covering the entire –200°C to +760°C temperature range recommended for type J thermocouples while the AD597 can accommodate –200°C to +1250°C type K inputs. They have a calibration accuracy of ±4°C at an ambient temperature of 60°C and an ambient temperature stability specification of 0.05°C/°C from +25°C to +100°C.

None of the thermocouple amplifiers previously described compensate for thermocouple non-linearity, they only provide conditioning and voltage gain. High resolution ADCs such as the AD77XX family can be used to digitize the
thermocouple output directly, allowing a microcontroller to perform the transfer function linearization as shown in Figure 6.12. The two multiplexed inputs to the ADC are used to digitize the thermocouple voltage and the cold-junction temperature sensor outputs directly. The input PGA gain is programmable from 1 to 128, and the ADC resolution is between 16 and 22 bits (depending upon the particular ADC selected). The microcontroller performs both the cold-junction compensation and the linearization arithmetic.

![AD77XX ADC Used with TMP35 Temperature Sensor for CJC](image)

**Figure 6.12**

**Resistance Temperature Detectors (RTDs)**

The Resistance Temperature Detector, or the RTD, is a sensor whose resistance changes with temperature. Typically built of a platinum (Pt) wire wrapped around a ceramic bobbin, the RTD exhibits behavior which is more accurate and more linear over wide temperature ranges than a thermocouple. Figure 6.13 illustrates the temperature coefficient of a 100Ω RTD and the Seebeck coefficient of a Type S thermocouple. Over the entire range (approximately –200°C to +850°C), the RTD is a more linear device. Hence, linearizing an RTD is less complex.
RESISTANCE TEMPERATURE DETECTORs (RTD)

- Platinum (Pt) the Most Common
- 100Ω, 1000Ω Standard Values
- Typical TC = 0.385% / °C
  0.385Ω / °C for 100Ω Pt RTD
- Good Linearity - Better than Thermocouple, Easily Compensated

Unlike a thermocouple, however, an RTD is a passive sensor and requires current excitation to produce an output voltage. The RTD's low temperature coefficient of 0.385%/°C requires similar high-performance signal conditioning circuitry to that used by a thermocouple; however, the voltage drop across an RTD is much larger than a thermocouple output voltage. A system designer may opt for large value RTDs with higher output, but large-valued RTDs exhibit slow response times. Furthermore, although the cost of RTDs is higher than that of thermocouples, they use copper leads, and thermoelectric effects from terminating junctions do not affect their accuracy. And finally, because their resistance is a function of the absolute temperature, RTDs require no cold-junction compensation.

Caution must be exercised using current excitation because the current through the RTD causes heating. This self-heating changes the temperature of the RTD and appears as a measurement error. Hence, careful attention must be paid to the design of the signal conditioning circuitry so that self-heating is kept below 0.5°C. Manufacturers specify self-heating errors for various RTD values and sizes in still and in moving air. To reduce the error due to self-heating, the minimum current should be used for the required system resolution, and the largest RTD value chosen that results in acceptable response time.

Another effect that can produce measurement error is voltage drop in RTD lead wires. This is especially critical with low-value 2-wire RTDs because the temperature coefficient and the absolute value of the RTD resistance are both small. If the RTD is located a long distance from the signal conditioning circuitry, then the lead resistance can be ohms or tens of ohms, and a small amount of lead resistance
can contribute a significant error to the temperature measurement. To illustrate this point, let us assume that a 100Ω platinum RTD with 30-gauge copper leads is located about 100 feet from a controller’s display console. The resistance of 30-gauge copper wire is 0.105Ω/ft, and the two leads of the RTD will contribute a total 21Ω to the network which is shown in Figure 6.14. This additional resistance will produce a 55°C error in the measurement! The leads’ temperature coefficient can contribute an additional, and possibly significant, error to the measurement. To eliminate the effect of the lead resistance, a 4-wire technique is used.

**A 100Ω Pt RTD WITH 100 FEET OF 30-GAUGE LEAD WIRES**

![Diagram of a 4-wire RTD connection]

RESISTANCE TC OF COPPER = 0.40%/°C @ 20°C

RESISTANCE TC OF Pt RTD = 0.385%/°C @ 20°C

Figure 6.14

In Figure 6.15, a 4-wire, or Kelvin, connection is made to the RTD. A constant current is applied though the FORCE leads of the RTD, and the voltage across the RTD itself is measured remotely via the SENSE leads. The measuring device can be a DVM or an instrumentation amplifier, and high accuracy can be achieved provided that the measuring device exhibits high input impedance and/or low input bias current. Since the SENSE leads do not carry appreciable current, this technique is insensitive to lead wire length. Sources of errors are the stability of the constant current source and the input impedance and/or bias currents in the amplifier or DVM.

RTDs are generally configured in a four-resistor bridge circuit. The bridge output is amplified by an instrumentation amplifier for further processing. However, high resolution measurement ADCs such as the AD77XX series allow the RTD output to be digitized directly. In this manner, linearization can be performed digitally, thereby easing the analog circuit requirements.
Figure 6.16 shows a 100Ω Pt RTD driven with a 400µA excitation current source. The output is digitized by one of the AD77XX series ADCs. Note that the RTD excitation current source also generates the 2.5V reference voltage for the ADC via the 6.25kΩ resistor. Variations in the excitation current do not affect the circuit accuracy, since both the input voltage and the reference voltage vary ratiometrically with the excitation current. However, the 6.25kΩ resistor must have a low temperature coefficient to avoid errors in the measurement. The high resolution of the ADC and the input PGA (gain of 1 to 128) eliminates the need for additional conditioning circuits.

The ADT70 is a complete Pt RTD signal conditioner which provides an output voltage of 5mV/°C when using a 1kΩ RTD (see Figure 6.17). The Pt RTD and the 1kΩ reference resistor are both excited with 1mA matched current sources. This allows temperature measurements to be made over a range of approximately –50°C to +800°C.

The ADT70 contains the two matched current sources, a precision rail-to-rail output instrumentation amplifier, a 2.5V reference, and an uncommitted rail-to-rail output op amp. A shutdown function is included for battery powered equipment that reduces the quiescent current from 3mA to 10µA. The gain or full-scale range for the Pt RTD and ADT70 system is set by a precision external resistor connected to the instrumentation amplifier. The uncommitted op amp may be used for scaling the internal voltage reference, providing a "Pt RTD open" signal or "over temperature" warning, providing a heater switching signal, or other external conditioning determined by the user. The ADT70 is specified for operation from –40°C to +125°C and is available in 20-pin DIP and SOIC packages.
INTERFACING A Pt RTD TO A HIGH RESOLUTION ADC

Figure 6.16

CONDITIONING THE PLATINUM RTD USING THE ADT70

Figure 6.17
Thermistors

Similar in function to the RTD, thermistors are low-cost temperature-sensitive resistors and are constructed of solid semiconductor materials which exhibit a positive or negative temperature coefficient. Although positive temperature coefficient devices are available, the most commonly used thermistors are those with a negative temperature coefficient. Figure 6.18 shows the resistance-temperature characteristic of a commonly used NTC (Negative Temperature Coefficient) thermistor. The thermistor is highly non-linear and, of the three temperature sensors discussed, is the most sensitive.

The thermistor's high sensitivity (typically, –44,000ppm/°C at 25°C, as shown in Figure 6.19), allows it to detect minute variations in temperature which could not be observed with an RTD or thermocouple. This high sensitivity is a distinct advantage over the RTD in that 4-wire Kelvin connections to the thermistor are not needed to compensate for lead wire errors. To illustrate this point, suppose a 10kΩ NTC thermistor, with a typical 25°C temperature coefficient of –44,000ppm/°C, were substituted for the 100Ω Pt RTD in the example given earlier, then a total lead wire resistance of 21Ω would generate less than 0.05°C error in the measurement. This is roughly a factor of 500 improvement in error over an RTD.
However, the thermistor's high sensitivity to temperature does not come without a price. As was shown in Figure 6.18, the temperature coefficient of thermistors does not decrease linearly with increasing temperature as it does with RTDs; therefore, linearization is required for all but the narrowest of temperature ranges. Thermistor applications are limited to a few hundred degrees at best because they are more susceptible to damage at high temperatures. Compared to thermocouples and RTDs, thermistors are fragile in construction and require careful mounting procedures to prevent crushing or bond separation. Although a thermistor's response time is short due to its small size, its small thermal mass makes it very sensitive to self-heating errors.

Thermistors are very inexpensive, highly sensitive temperature sensors. However, we have shown that a thermistor's temperature coefficient varies from $-44,000$ ppm/$^\circ$C at 25°C to $-29,000$ ppm/$^\circ$C at 100°C. Not only is this non-linearity the largest source of error in a temperature measurement, it also limits useful applications to very narrow temperature ranges if linearization techniques are not used.

It is possible to use a thermistor over a wide temperature range only if the system designer can tolerate a lower sensitivity to achieve improved linearity. One approach to linearizing a thermistor is simply shunting it with a fixed resistor. Paralleling the thermistor with a fixed resistor increases the linearity significantly. As shown in Figure 6.20, the parallel combination exhibits a more linear variation with temperature compared to the thermistor itself. Also, the sensitivity of the combination still is high compared to a thermocouple or RTD. The primary
disadvantage to this technique is that linearization can only be achieved within a narrow range.

**LINEARIZATION OF NTC THERMISTOR USING A 5.17kΩ SHUNT RESISTOR**

![Graph showing the linearization of a NTC thermistor](image)

**Figure 6.20**

The value of the fixed resistor can be calculated from the following equation:

\[
R = \frac{RT2 \cdot (RT1 + RT3) - 2 \cdot RT1 \cdot RT3}{RT1 + RT3 - 2 \cdot RT2},
\]

where RT1 is the thermistor resistance at T1, the lowest temperature in the measurement range, RT3 is the thermistor resistance at T3, the highest temperature in the range, and RT2 is the thermistor resistance at T2, the midpoint, \(T2 = \frac{(T1 + T3)}{2}\).

For a typical 10kΩ NTC thermistor, RT1 = 32,650Ω at 0°C, RT2 = 6,532Ω at 35°C, and RT3 = 1,752Ω at 70°C. This results in a value of 5.17kΩ for R. The accuracy needed in the signal conditioning circuitry depends on the linearity of the network. For the example given above, the network shows a non-linearity of \(-2.3°C/ +2.0°C\).

The output of the network can be applied to an ADC to perform further linearization as shown in Figure 6.21. Note that the output of the thermistor network has a slope of approximately \(-10mV/°C\), which implies a 12-bit ADC has more than sufficient resolution.
Modern semiconductor temperature sensors offer high accuracy and high linearity over an operating range of about –55°C to +150°C. Internal amplifiers can scale the output to convenient values, such as 10mV/°C. They are also useful in cold-junction-compensation circuits for wide temperature range thermocouples.

All semiconductor temperature sensors make use of the relationship between a bipolar junction transistor’s (BJT) base-emitter voltage to its collector current:

\[ V_{BE} = \frac{kT}{q} \ln \left( \frac{I_c}{I_s} \right) \]

where \( k \) is Boltzmann’s constant, \( T \) is the absolute temperature, \( q \) is the charge of an electron, and \( I_s \) is a current related to the geometry and the temperature of the transistors. (The equation assumes a voltage of at least a few hundred mV on the collector, and ignores Early effects.)

If we take \( N \) transistors identical to the first (see Figure 6.22) and allow the total current \( I_c \) to be shared equally among them, we find that the new base-emitter voltage is given by the equation

\[ V_N = \frac{kT}{q} \ln \left( \frac{I_c}{N \cdot I_s} \right) \]
**BASIC RELATIONSHIPS FOR SEMICONDUCTOR TEMPERATURE SENSORS**

![Diagrams: One Transistor and N Transistors](image)

\[ V_{BE} = \frac{kT}{q} \ln \left( \frac{I_C}{I_S} \right) \]

\[ V_N = \frac{kT}{q} \ln \left( \frac{I_C}{N \cdot I_S} \right) \]

\[ V_{BE} - V_N = \frac{kT}{q} \ln(N) \]

INDEPENDENT OF \( I_C, I_S \)

**Figure 6.22**

Neither of these circuits is of much use by itself because of the strongly temperature dependent current \( I_S \), but if we have equal currents in one BJT and \( N \) similar BJTs then the expression for the difference between the two base-emitter voltages is proportional to absolute temperature and does not contain \( I_S \).

\[ V_{BE} - V_N = \frac{kT}{q} \ln \left( \frac{I_C}{I_S} \right) - \frac{kT}{q} \ln \left( \frac{I_C}{N \cdot I_S} \right) \]

\[ V_{BE} - V_N = \frac{kT}{q} \left[ \ln \left( \frac{I_C}{I_S} \right) - \ln \left( \frac{I_C}{N \cdot I_S} \right) \right] \]

\[ V_{BE} - V_N = \frac{kT}{q} \ln \left( \frac{I_C}{I_S} / \frac{I_C}{N \cdot I_S} \right) = \frac{kT}{q} \ln(N) \]

The circuit shown in Figure 6.23 implements the above equation and is known as the "Brokaw Cell" (see Reference 10). The voltage \( V_{BE} - V_N \) appears across resistor \( R_2 \). The emitter current in \( Q_2 \) is therefore \( (V_{BE} - V_N)/R_2 \). The op amp's servo loop and the resistors, \( R \), force the same current to flow through \( Q_1 \). The \( Q_1 \) and \( Q_2 \) currents are equal and are summed and flow into resistor \( R_1 \). The corresponding voltage developed across \( R_1 \) is proportional to absolute temperature (PTAT) and given by:
The bandgap cell reference voltage, $V_{\text{BANDGAP}}$, appears at the base of $Q1$ and is the sum of $V_{\text{BE}(Q1)}$ and $V_{\text{PTAT}}$. $V_{\text{BE}(Q1)}$ is complementary to absolute temperature (CTAT), and summing it with $V_{\text{PTAT}}$ causes the bandgap voltage to be constant with respect to temperature (assuming proper choice of $R1/R2$ ratio and $N$ to make the bandgap voltage equal to 1.205V). This circuit is the basic band-gap temperature sensor, and is widely used in semiconductor temperature sensors.

**Current and Voltage Output Temperature Sensors**

The concepts used in the bandgap temperature sensor discussion above can be used as the basis for a variety of IC temperature sensors to generate either current or voltage outputs. The AD592 and TMP17 (see Figure 6.24) are current output sensors which have scale factors of 1µA/K. The sensors do not require external calibration and are available in several accuracy grades. The AD592 is available in three accuracy grades. The highest grade version (AD592CN) has a maximum error @ 25°C of ±0.5°C and ±1.0°C error from −25°C to +105°C. Linearity error is ±0.35°C. The TMP17 is available in two accuracy grades. The highest grade version (TMP17F) has a maximum error @ 25°C of ±2.5°C and ±3.5°C error from −40°C to +105°C. Typical linearity error is ±0.5°C. The AD592 is available in a TO-92 package and the TMP17 in an SO-8 package.

- ±2.5°C Max Error @ 25°C, ±3.5°C Error Over Temp, ±0.5°C Typical Nonlinearity (TMP17F)
- AD592 Specified from –25°C to +105°C
- TMP17 Specified from –40°C to +105°C

Figure 6.24

RATIOMETRIC VOLTAGE OUTPUT SENSORS

![Ratiometric Voltage Output Schematic]

\[ V_{OUT} = \frac{V_S}{3.3V} \times \left( 0.25V + \frac{28mV}{\circ C} \times T_A \right) \]

Figure 6.25
In some cases, it is desirable for the output of a temperature sensor to be ratiometric with its supply voltage. The AD22103 (see Figure 6.25) has an output that is ratiometric with its supply voltage (nominally 3.3V) according to the equation:

$$V_{OUT} = \frac{V_S}{3.3V} \times \left( 0.25V + \frac{28mV}{°C} \times T_A \right).$$

The circuit shown in Figure 6.25 uses the AD22103 power supply as the reference to the ADC, thereby eliminating the need for a precision voltage reference. The AD22103 is specified over a range of 0°C to +100°C and has an accuracy better than ±2.5°C and a linearity better than ±0.5°C.

The TMP35/TMP36/TMP37 are low voltage (2.7V to 5.5V) SOT-23 (5-pin), SO-8, or TO-92 packaged voltage output temperature sensors with a 10mV/°C (TMP35/36) or 20mV/°C (TMP37) scale factor (see Figure 6.26). Supply current is below 50µA, providing very low self-heating (less than 0.1°C in still air). A shutdown feature is provided which reduces the current to 0.5µA.

The TMP35 provides a 250mV output at +25°C and reads temperature from +10°C to +125°C. The TMP36 is specified from –40°C to +125°C, and provides a 750mV output at 25°C. Both the TMP35 and TMP36 have an output scale factor of +10mV/°C. The TMP37 is intended for applications over the range +5°C to +100°C, and provides an output scale factor of 20mV/°C. The TMP37 provides a 500mV output at +25°C.
The ADT45/ADT50 are voltage output temperature sensors packaged in a SOT-23-3 package designed for an operating voltage of 2.7V to 12V (see Figure 6.27). The devices are specified over the range of –40ºC to +125ºC. The output scale factor for both devices is 10mV/ºC. Typical accuracies are ±1ºC at +25ºC and ±2ºC over the –40ºC to +125ºC range. The ADT45 provides a 250mV output at +25ºC and is specified for temperature from 0ºC to +100ºC. The ADT50 provides a 750mV output at +25ºC and is specified for temperature from –40ºC to +125ºC.

**ADT45/ADT50 ABSOLUTE VOLTAGE OUTPUT SENSORS**

- **VOUT:**
  - ADT45, 250mV @ 25ºC, 10mV/ºC Scale Factor
  - ADT50, 750mV @ 25ºC, 10mV/ºC Scale Factor
- ±2ºC Error Over Temp (Typical), ±0.5ºC Non-Linearity (Typical)
- Specified –40ºC to +125ºC
- 60µA Quiescent Current

If the ADT45/ADT50 sensors are thermally attached and protected, they can be used in any temperature measurement application where the maximum temperature range of the medium is between –40ºC to +125ºC. Properly cemented or glued to the surface of the medium, these sensors will be within 0.01ºC of the surface temperature. Caution should be exercised, as any wiring to the device can act as heat pipes, introducing errors if the surrounding air-surface interface is not isothermal. Avoiding this condition is easily achieved by dabbing the leads of the sensor and the hookup wires with a bead of thermally conductive epoxy. This will ensure that the ADT45/ADT50 die temperature is not affected by the surrounding air temperature.
In the SOT-23-3 package, the thermal resistance junction-to-case, $\theta_{JC}$, is 180°C/W. The thermal resistance case-to-ambient, $\theta_{CA}$, is the difference between $\theta_{JA}$ and $\theta_{JC}$, and is determined by the characteristics of the thermal connection. With no air flow and the device soldered on a PC board, $\theta_{JA}$ is 300°C/W. The temperature sensor’s power dissipation, $P_D$, is the product of the total voltage across the device and its total supply current (including any current delivered to the load). The rise in die temperature above the medium’s ambient temperature is given by:

$$T_J = P_D \times (\theta_{JC} + \theta_{CA}) + T_A.$$

Thus, the die temperature rise of an unloaded ADT45/ADT50 (SOT-23-3 package) soldered on a board in still air at 25°C and driven from a +5V supply (quiescent current = 60µA, $P_D = 300\mu$W) is less than 0.09°C. In order to prevent further temperature rise, it is important to minimize the load current, always keeping it less than 100µA.

The transient response of the ADT45/ADT50 sensors to a step change in temperature is determined by the thermal resistances and the thermal mass of the die and the case. The thermal mass of the case varies with the measurement medium since it includes anything that is in direct contact with the package. In all practical cases, the thermal mass of the case is the limiting factor in the thermal response time of the sensor and can be represented by a single-pole RC time constant. Thermal mass is often considered the thermal equivalent of electrical capacitance.

The thermal time constant of a temperature sensor is defined to be the time required for the sensor to reach 63.2% of the final value for a step change in the temperature. Figure 6.28 shows the thermal time constant of the ADT45/ADT50 series of sensors with the SOT-23-3 package soldered to 0.338” x 0.307” copper PC board as a function of air flow velocity. Note the rapid drop from 32 seconds to 12 seconds as the air velocity increases from 0 (still air) to 100 LFPM. As a point of reference, the thermal time constant of the ADT45/ADT50 series in a stirred oil bath is less than 1 second, which verifies that the major part of the thermal time constant is determined by the case.

The power supply pin of these sensors should be bypassed to ground with a 0.1µF ceramic capacitor having very short leads (preferably surface mount) and located as close to the power supply pin as possible. Since these temperature sensors operate on very little supply current and could be exposed to very hostile electrical environments, it is important to minimize the effects of EMI/RFI on these devices. The effect of RFI on these temperature sensors is manifested as abnormal DC shifts in the output voltage due to rectification of the high frequency noise by the internal IC junctions. In those cases where the devices are operated in the presence of high frequency radiated or conducted noise, a large value tantalum electrolytic capacitor (>2.2µF) placed across the 0.1µF ceramic may offer additional noise immunity.
**Digital Output Temperature Sensors**

Temperature sensors which have digital outputs have a number of advantages over those with analog outputs, especially in remote applications. Opto-isolators can also be used to provide galvanic isolation between the remote sensor and the measurement system. A voltage-to-frequency converter driven by a voltage output temperature sensor accomplishes this function, however, more sophisticated ICs are now available which are more efficient and offer several performance advantages.

The TMP03/TMP04 digital output sensor family includes a voltage reference, VPTAT generator, sigma-delta ADC, and a clock source (see Figure 6.29). The sensor output is digitized by a first-order sigma-delta modulator, also known as the "charge balance" type analog-to-digital converter. This converter utilizes time-domain oversampling and a high accuracy comparator to deliver 12 bits of effective accuracy in an extremely compact circuit.

The output of the sigma-delta modulator is encoded using a proprietary technique which results in a serial digital output signal with a mark-space ratio format (see Figure 6.30) that is easily decoded by any microprocessor into either degrees centigrade or degrees Fahrenheit, and readily transmitted over a single wire. Most importantly, this encoding method avoids major error sources common to other modulation techniques, as it is clock-independent. The nominal output frequency is 35Hz at +25°C, and the device operates with a fixed high-level pulse width (T1) of 10ms.
**TEMPERATURE SENSORS**

**DIGITAL OUTPUT SENSORS: TMP03/04**

$+V_S = 4.5 \text{ TO } 7V$

- **REFERENCE VOLTAGE**

**Figure 6.29**

**TMP03/TMP04 OUTPUT FORMAT**

![Diagram of TMP03/TMP04 output format](image)

$$\text{TEMPERATURE (°C)} = 235 - \left( \frac{400 \times T1}{T2} \right)$$

$$\text{TEMPERATURE (°F)} = 455 - \left( \frac{720 \times T1}{T2} \right)$$

- T1 Nominal Pulse Width = 10ms
- ±1.5°C Error Over Temp, ±0.5°C Non-Linearity (Typical)
- Specified −40°C to +100°C
- Nominal T1/T2 @ 0°C = 60%
- Nominal Frequency @ +25°C = 35Hz
- 6.5mW Power Consumption @ 5V
- TO-92, SO-8, or TSSOP Packages

**Figure 6.30**
The TMP03/TMP04 output is a stream of digital pulses, and the temperature information is contained in the mark-space ratio per the equations:

\[
\text{Temperature (°C)} = 235 - \left( \frac{400 \times T_1}{T_2} \right) \\
\text{Temperature (°F)} = 455 - \left( \frac{720 \times T_1}{T_2} \right).
\]

Popular microcontrollers, such as the 80C51 and 68HC11, have on-chip timers which can easily decode the mark-space ratio of the TMP03/TMP04. A typical interface to the 80C51 is shown in Figure 6.31. Two timers, labeled Timer 0 and Timer 1 are 16 bits in length. The 80C51’s system clock, divided by twelve, provides the source for the timers. The system clock is normally derived from a crystal oscillator, so timing measurements are quite accurate. Since the sensor’s output is ratiometric, the actual clock frequency is not important. This feature is important because the microcontroller's clock frequency is often defined by some external timing constraint, such as the serial baud rate.

Software for the sensor interface is straightforward. The microcontroller simply monitors I/O port P1.0, and starts Timer 0 on the rising edge of the sensor output. The microcontroller continues to monitor P1.0, stopping Timer 0 and starting Timer 1 when the sensor output goes low. When the output returns high, the sensor's T1 and T2 times are contained in registers Timer 0 and Timer 1, respectively. Further software routines can then apply the conversion factor shown in the equations above and calculate the temperature.
The TMP03/TMP04 are ideal for monitoring the thermal environment within electronic equipment. For example, the surface mounted package will accurately reflect the thermal conditions which affect nearby integrated circuits. The TO-92 package, on the other hand, can be mounted above the surface of the board to measure the temperature of the air flowing over the board.

The TMP03 and TMP04 measure and convert the temperature at the surface of their own semiconductor chip. When they are used to measure the temperature of a nearby heat source, the thermal impedance between the heat source and the sensor must be considered. Often, a thermocouple or other temperature sensor is used to measure the temperature of the source, while the TMP03/TMP04 temperature is monitored by measuring T1 and T2. Once the thermal impedance is determined, the temperature of the heat source can be inferred from the TMP03/TMP04 output.

One example of using the TMP04 to monitor a high power dissipation microprocessor or other IC is shown in Figure 6.32. The TMP04, in a surface mount package, is mounted directly beneath the microprocessor's pin grid array (PGA) package. In a typical application, the TMP04's output would be connected to an ASIC where the mark-space ratio would be measured. The TMP04 pulse output provides a significant advantage in this application because it produces a linear temperature output, while needing only one I/O pin and without requiring an ADC.

**MONITORING HIGH POWER MICROPROCESSOR OR DSP WITH TMP04**

![Diagram of TMP04 monitoring a high power microprocessor](image)

**Figure 6.32**

**Thermostatic Switches and Setpoint Controllers**

Temperature sensors used in conjunction with comparators can act as thermostatic switches. ICs such as the ADT05 accomplish this function at low cost and allow a single external resistor to program the setpoint to 2°C accuracy over a range of –40°C to +150°C (see Figure 6.33). The device asserts an open collector output when the ambient temperature exceeds the user-programmed setpoint temperature. The ADT05 has approximately 4°C of hysteresis which prevents rapid thermal on/off cycling. The ADT05 is designed to operate on a single supply voltage from +2.7V to
+7.0V facilitating operation in battery powered applications as well as industrial control systems. Because of low power dissipation (200µW @ 3.3V), self-heating errors are minimized, and battery life is maximized. An optional internal 200kΩ pull-up resistor is included to facilitate driving light loads such as CMOS inputs.

The setpoint resistor is determined by the equation:

\[
R_{SET} = \frac{39\Omega^\circ C}{T_{SET}(^\circ C) + 281.6^\circ C} - 90.3\Omega.
\]

The setpoint resistor should be connected directly between the RSET pin (Pin 4) and the GND pin (Pin 5). If a ground plane is used, the resistor may be connected directly to this plane at the closest available point.

The setpoint resistor can be of nearly any resistor type, but its initial tolerance and thermal drift will affect the accuracy of the programmed switching temperature. For most applications, a 1% metal-film resistor will provide the best tradeoff between cost and accuracy. Once \( R_{SET} \) has been calculated, it may be found that the calculated value does not agree with readily available standard resistors of the chosen tolerance. In order to achieve a value as close as possible to the calculated value, a compound resistor can be constructed by connecting two resistors in series or parallel.

**ADT05 THERMOSTATIC SWITCH**

- ±2°C Setpoint Accuracy
- 4°C Preset Hysteresis
- Specified Operating Range: –40°C to +150°C
- Power Dissipation: 200µW @ 3.3V

Figure 6.33
The TMP01 is a dual setpoint temperature controller which also generates a PTAT output voltage (see Figure 6.34 and 6.35). It also generates a control signal from one of two outputs when the device is either above or below a specific temperature range. Both the high/low temperature trip points and hysteresis band are determined by user-selected external resistors.

**TMP01 PROGRAMMABLE SETPOINT CONTROLLER**

![Diagram of TMP01](image)

Figure 6.34

The TMP01 consists of a bandgap voltage reference combined with a pair of matched comparators. The reference provides both a constant 2.5V output and a PTAT output voltage which has a precise temperature coefficient of 5mV/K and is 1.49V (nominal) at +25°C. The comparators compare VPTAT with the externally set temperature trip points and generate an open-collector output signal when one of their respective thresholds has been exceeded.

Hysteresis is also programmed by the external resistor chain and is determined by the total current drawn out of the 2.5V reference. This current is mirrored and used to generate a hysteresis offset voltage of the appropriate polarity after a comparator has been tripped. The comparators are connected in parallel, which guarantees that there is no hysteresis overlap and eliminates erratic transitions between adjacent trip zones.

The TMP01 utilizes laser trimmed thin-film resistors to maintain a typical temperature accuracy of ±1°C over the rated temperature range. The open-collector outputs are capable of sinking 20mA, enabling the TMP01 to drive control relays directly. Operating from a +5V supply, quiescent current is only 500µA maximum.
**Temperature Sensors**

**TMP01 Setpoint Point Controller Key Features**

- $V_C$: 4.5 to 13.2V
- Temperature Output: VPTAT, +5mV/K
- Nominal 1.49V Output @ 25°C
- $\pm1^\circ$C Typical Accuracy Over Temperature
- Specified Operating Range: –55°C to +125°C
- Resistor-Programmable Hysteresis
- Resistor-Programmable Setpoints
- Precision 2.5V $\pm8$mV Reference
- 400$\mu$A Quiescent Current, 1$\mu$A in Shutdown
- Packages: 8-Pin Dip, 8-Pin SOIC, 8-Pin TO-99
- Other Setpoint Controllers:
  - Dual Setpoint Controllers: ADT20/21/22
    (3V Versions of TMP01 with Internal Hysteresis)
  - Quad Setpoint Controller: ADT14

Figure 6.35

The ADT20/21/22-series are similar to the TMP01 but have internal hysteresis and are designed to operate on a 3V supply. A quad (ADT14) setpoint controller is also available.

**An Airflow Monitor Based on the TMP12**

For large power dissipation and/or to maintain low $T_J$'s, forced air movement can be used to increase air flow and aid in heat removal. In its most simple form this can consist of a continuously or thermostatically operated fan, directed across high temperature, high wattage dissipation devices such as CPUs, DSP chips, etc.

Quite often however, more sophisticated temperature control is necessary. Recent temperature monitoring and control ICs such as the TMP12, an airflow temperature sensor IC, lend themselves to such applications.

The TMP12 includes on chip two comparators, a voltage reference, a temperature sensor and a heater. The heater is used to force a predictable internal temperature rise, to match a power IC such as a microprocessor. The temperature sensing and control portions of the IC can then be programmed to respond to the temperature changes and control an external fan, so as to maintain some range of temperature. Compared to a simple thermostat, this allows infinite resolution of user control for control points and ON/OFF hysteresis.

The device is placed in an air stream near the power IC, such that both see the same stream of air, and will thus have like temperature profiles, assuming proper control of the stream. This is shown in basic form by the layout diagram of Figure 6.36.
SYSTEM USE OF TMP12 AIRFLOW SENSOR

- TMP12 HAS INTERNAL 250mW HEATER
- TMP12 INTERNAL TEMPERATURE PROPORTIONAL TO AIR FLOW
- TMP12 INTERNAL TEMPERATURE PROPORTIONAL TO POWER IC TEMPERATURE

Figure 6.36

TMP12 TEMPERATURE RELATIONSHIPS

A. TMP12 DIE TEMP NO AIR FLOW
B. HIGH SET POINT
C. LOW SET POINT
D. TMP12 DIE TEMP MAX AIR FLOW
E. SYSTEM AMBIENT TEMPERATURE

Figure 6.37
TEMPERATURE SENSORS

With the TMP12’s internal 250mW heater ON and no airflow, the TMP12 thermal profile will look like the curve “A” of Figure 6.37, and will show a 20°C rise above $T_A$. When airflow is provided, this same dissipation results in a lower temperature, “D”. In programming the device for airspeed control, the designer can set up to two switch points, shown here symbolically by “B” and “C”, which are HIGH and LOW setpoints, respectively. The basic idea is that when the IC substrate reaches point B in temperature, the external fan will be turned on to create the air stream, and lower the temperature. If the overall system setup is reasonable in terms of thermal profiling, this small IC can thus be used to indirectly control another larger and independent power source with regard to its temperature. Note that the dual mode control need not necessarily be used, in all applications. An unused comparator is simply wired high or low.

Figure 6.38 shows a circuit diagram using the TMP12 as a general purpose controller. The device is connected to a 5V supply, which is also used to power a control relay and the TMP12’s internal heater at pin 5. Setpoint programming of the TMP12 is accomplished by the resistor string at pins 4 through 1, R1 - R3. These resistors establish a current drain from the internal reference source at pin 4, which sets up a reference current, $I_{REF}$, which is set as:

$$I_{REF} = (5\mu A/°C \times THYS) + 7\mu A$$

In this expression, $THYS$ is the hysteresis temperature swing desired about the setpoint, in °C, and the $7\mu A$ is recommended minimum loading of the reference. For a 2°C hysteresis for example, $I_{REF}$ is 17μA; for 5°C, it would be 32μA.

Given a desired setpoint temperature in °C, the setpoint can be converted to a corresponding voltage. Although not available externally, the internal temperature dependent voltage of the TMP12 is scaled at 5mV/°C, and is equal to 1.49V at 25°C.

To convert a setpoint temperature to a voltage $V_{SETPOINT}$,

$$V_{SETPOINT} = 1.49V + \left[ 5mV/°C \times (TSETPOINT - T_{25}) \right]$$

where $TSETPOINT$ is the desired setpoint temperature, and $T_{25}$ is 25°C. For a 50°C high setpoint, this works out to be $V_{SETPOINT(HI)} = 1.615V$. For a lower setpoint of 35°C, the voltage $V_{SETPOINT(LO)}$ would be 1.59V.

The divider resistors are then chosen to draw the required current $I_{REF}$ while setting the two tap voltages corresponding to $V_{SETPOINT(HI)}$ and $V_{SETPOINT(LO)}$.

$$R_{TOTAL} = \frac{V_{REF}}{I_{REF}} = \frac{2.5V}{I_{REF}}$$

$$R1 = \frac{V_{REF} - V_{SETPOINT(HI)}}{I_{REF}} = \frac{2.5V - V_{SETPOINT(HI)}}{I_{REF}}$$

$$R2 = \frac{V_{SETPOINT(HI)} - V_{SETPOINT(LO)}}{I_{REF}}$$

$$R3 = \frac{V_{SETPOINT(LO)}}{I_{REF}}$$
In the example of the figure, the resulting standard values for R1 - R3 correspond to the temperature/voltage setpoint examples noted above. Ideal 1% values shown give resistor related errors of only 0.1°C from ideal. Note that this error is independent of the TMP12 temperature errors, which are ±2°C.

As noted above, both comparators of the device need not always be used, and in this case the lower comparator output is not used. For a single point 50°C controller, the 35°C setpoint is superfluous. One resistor can be eliminated by making R2 + R3 a single value of 95.3kΩ and connecting pin 3 to GND. Pin 6 should be left as a no-connect. If a greater hysteresis is desired, the resistor values will be proportionally lowered.

It is also important to minimize potential parasitic temperature errors associated with the TMP12. Although the open-collector outputs can sink up to 20mA, it is advised that currents be kept low at this node, to limit any additional temperature rise. The Q1 - Q2 transistor buffer shown in the figure raises the current drive to 100mA, allowing a 50Ω/5V coil to be driven. The relay type shown is general purpose, and many other power interfaces are possible with the TMP12. If used as shown, the relay contacts would be used to turn on a fan for airflow when the active low output at pin 7 changes, indicating the upper setpoint threshold.

A basic assumption of the TMP12’s operation is that it will “mimic” another device in temperature rise. Therefore, a practical working system must be arranged and tested for proper airflow channeling, minimal disturbances from adjacent devices, etc. Some experimentation should be expected before a final setup will result.
